Our results concerning the prognostic significance of ventricular ectopic activity are consistent with the data of Schulze et al.[3] They found that premature ventricular complexes recorded in ambulatory electrocardiograms at hospital discharge after infarction were associated with sudden death in the next 6 months *only* in patients with coexistent left ventricular dysfunction (that is, an ejection fraction of less than 0.4). No deaths occurred in patients with complex ventricular ectopic activity and an ejection fraction of less than 0.4. Like Schulze et al., we found ventricular ectopic activity recorded on ambulatory electrocardiography to have little prognostic significance in patients free of clinically significant left ventricular dysfunction. By contrast, in most studies that have shown an association between ventricular ectopic activity on ambulatory electrocardiography and subsequent coronary events, clinical heart failure has been present in approximately 20 to 50 percent of cases.[1,9,22]

Prognosis of ventricular ectopic activity versus exercise-induced ischemia: In patients without clinically significant left ventricular dysfunction, premature ventricular complexes do not appear to be the most prognostically relevant abnormality: we found exercise-induced ischemic S-T segment depression of 0.2 mV or greater or a low peak work load to have prognostic significance whereas exercise-induced premature ventricular complexes did not. This study extends our previous finding[24] that exercise-induced ischemia on serial testing between 3 and 11 weeks after infarction was associated with subsequent cardiac events whereas exercise-induced ventricular ectopic activity was not. We have confirmed the prognostic usefulness of exercise-induced ischemic S-T segment depression and low peak treadmill work load with life table methods in an additional 105 men who were followed up without ambulatory electrocardiographic monitoring 1 to 30 months after uncomplicated myocardial infarction.[17] Thus, ambulatory monitoring and treadmill exercise testing should not be considered as merely redundant techniques for detecting ventricular ectopic activity; subsequent coronary events may be more strongly reflected by other treadmill variables than by ventricular ectopic activity. Further experience is needed to establish the relative prognostic value of ambulatory electrocardiography and treadmill exercise testing after myocardial infarction.

Other clinical implications: Ambulatory monitoring and treadmill exercise testing may find their optimal application in different patient subsets. In patients with clinical heart failure, ambulatory monitoring appears the better technique because of its greater safety and proved efficacy in the detection of prognostically important ventricular ectopic activity. In patients without clinical heart failure, treadmill testing may be the better technique: In these patients exercise-induced premature ventricular complexes appear to be of lesser prognostic significance than exercise-induced S-T segment depression. The prognostic importance of S-T segment depression detected by ambulatory monitoring remains to be established in patients in the postinfarction period. Finally, our results indicate that exercise testing performed as soon as 3 weeks after clinically uncomplicated infarction yields prognostic information not available from exercise testing performed at a later phase of convalescence such as 11 weeks and thereafter.

APPENDIX

Details of Stepwise Multiple Logistic Regression Analysis

First, the association between candidate variables and clinical events is expressed by univariate correlation coefficients. Next, the variable with the highest univariate correlation

coefficient is selected as the "most valuable variable." The event rate for patients with this characteristic is compared with the event rate of those without the characteristic using a chi square test. If the chi square is significant, the process continues. The most valuable variable is combined with each of the remaining variables, one at a time, and a correlation with events is obtained for each pair of variables. Again, the variable with the highest correlation coefficient when combined with the previously selected variables is designated "next most valuable." The event rate for patients with this combination of selected variables is then compared with the event rate for those without these characteristics, using the chi square technique. If the increase in chi square is significantly greater than that calculated on the previous iteration, the most recently chosen variable enters the pool of "valuable variables." The process is then repeated for the remaining variables. When the most recently selected variable no longer yields a significant increase in the chi square statistic, this variable is excluded from further consideration and the process stops.

Frequently, the variables that unilaterally are highly associated with outcome are not selected because the information they contain is better expressed by other previously selected variables. Thus, the value of a given variable represents not only its univariate correlation with events but also its independence from other previously selected variables. This process results in a combination of variables which is significantly related to clinical outcome.

Each variable χ_i is assigned a coefficient β_i which expresses its relative prognostic utility. Each variable and its coefficient then enters an exponential equation which expresses the probability of an event within a given time:

$$\text{Probability} = \frac{1}{1 + e^{-(\text{alpha} + \sum \text{beta}_i \chi_i)}}$$

A constant, alpha, completes the equation.

Ventricular Compliance in Ischemic Right Ventricular Dysfunction

ISABEL COMA-CANELLA, MD
JOSE LOPEZ-SENDON, MD

Madrid, Spain

Ischemic right ventricular dysfunction was diagnosed in 54 patients with acute myocardial infarction who had a right atrial pressure disproportionately increased in relation to the pulmonary capillary pressure. The right atrial pressure curve in 40 patients (74 percent) was M- or W-shaped, termed a noncompliant pattern, and was similar to the pattern found in constrictive pericarditis. Kussmaul's sign was found in the patients whose respiration was recorded. This pattern, which represents poor right ventricular compliance, was severe in 30 cases (*y* descent > *x* descent) and slight in 10 cases (*y* descent = *x* descent). Its duration was variable, ranging from days to years.

Of the 54 patients, 32 (59 percent) had a low output syndrome, diagnosed in the presence of a cardiac index of less than 2.2 liters/min per m^2, with signs of poor tissue perfusion. The severe noncompliant pattern was significantly related to the presence of a low output syndrome ($p < 0.01$) and mortality from this cause ($p < 0.05$). The jugular venous tracing pulse had a pattern similar to that of the right atrial pressure recording and therefore may be valuable in the noninvasive diagnosis of right ventricular dysfunction and in the study of the evolution of the noncompliant pattern and, hence, of ventricular compliance.

The appropriate diagnosis and treatment of right ventricular dysfunction secondary to right ventricular infarction has changed the prognosis of an important group of patients with acute myocardial infarction.[1,2] Usually these patients have posterior wall necrosis of both ventricles,[3–8] although the term right ventricular infarction is commonly used.

During the last few years, the clinical, hemodynamic and anatomic features of right ventricular infarction have been described.[9–19] Its principal hemodynamic characteristic is a right atrial pressure disproportionately increased in relation to left ventricular filling pressure.[10,11] Some investigators[20–25] have also reported the presence of a poor pattern of right ventricular compliance with a pressure wave form in the right heart chambers similar to that observed in constrictive pericarditis and restrictive cardiomyopathy. This report examines the presentation of the noncompliant pattern in ischemic right ventricular dysfunction, its relation to the patient's prognosis and the possibility of its diagnosis by means of a simple noninvasive procedure.

Methods

Patients: We studied 54 patients with acute myocardial infarction and right ventricular dysfunction. All 54 were admitted to the coronary care unit between August 1977 and April 1979 within the first 24 hours of an inferior or posterior infarction. Fifty were men and four women; their age ranged from 35 to 92 years (mean 63).

Hemodynamic measurements: Right hemodynamic monitoring was performed in every patient for a period of 1 to 6 days. A Swan-Ganz thermodilution catheter was inserted into the pulmonary artery through the right antecubital

$\overline{PCP}$ = mean pulmonary capillary pressure (mm Hg); $\overline{RAP}$ = mean right atrial pressure (mm Hg).

vein. Right atrial, pulmonary artery and pulmonary capillary wedge pressures were recorded with a Hewlett-Packard model 1280 transducer and a Siemens Elema Mingograph, model 34. Whenever possible, right ventricular pressure was measured on withdrawal of the catheter.

Cardiac output was determined with the thermodilution technique, using an Edwards model 9500 computer. In every case, at least three successive determinations were made, and the average value was calculated. *Cardiac index* (CI) was calculated in liters/min per m^2 according to the formula CI = CO/BSA, where CO is cardiac output in liters/min and BSA is body surface area in square meters.

In every patient, the jugular venous pulse was recorded with an Electronic for Medicine Echo IV. In 15 patients, respiration was recorded simultaneously with the right atrial pressure with use of a Bouck-Brech receiver.

Nomenclature and diagnostic criteria: The diagnosis of ischemic right ventricular dysfunction was made when the level of right atrial pressure was high (greater than 10 mm Hg), with a disproportionate increase in relation to pulmonary capillary pressure, in basal conditions or after volume overloading. This test was performed by quick intravenous infusion of dextran-40 until right atrial pressure was greater than 10 mm Hg. The increase in right atrial pressure was considered disproportionate when it was equal to, exceeded or was slightly (1 to 5 mm Hg) lower than the level of pulmonary capillary pressure. Patients with a pressure gradient between the pulmonary arterial diastolic pressure and pulmonary capillary pressure were not included in the study.

The term "noncompliant pattern" was used when right atrial pressure showed an M- or W-wave form resembling that of constrictive pericarditis or restrictive cardiomyopathy. Noncompliance was considered severe or mild, respectively, when the *y* descent was deeper than or equal to the *x* descent.

Low output syndrome was defined[26] as a cardiac index below 2.2 liters/min per m^2 with evidence of reduced tissue perfusion such as mental impairment and oliguria or anuria. Some of the patients manifested shock,[27] but others had no signs of peripheral vasoconstriction. For this reason the term "low output syndrome" rather than "shock" has been used.

Data analysis: Statistical analysis was performed using the Fisher's Exact test.

Results

Noncompliant hemodynamic pattern: Table I shows the mean right atrial and pulmonary capillary pressures of every patient at the first hemodynamic determination that we considered diagnostic of right ventricular dysfunction. A noncompliant pattern was observed in 40 (74 percent) of the 54 patients. It was severe in 30 and mild in 10. The remaining 14 patients had a right atrial pressure with a normal contour or a W-shaped wave form, but the *x* descent was deeper than the *y* descent (Fig. 1). The mean (± standard deviation) right atrial pressure of these patients was 15.6 ± 3.1 mm Hg.

In 34 patients, the noncompliant pattern was present at the first hemodynamic determination; in the other 6, it appeared 1 or 2 days later. In three patients it was not present in basal conditions, but appeared in a mild form with a higher right atrial pressure (mean 15.3 ± 3.2 mm Hg). The mean right atrial pressure level in the remaining patients with a noncompliant pattern ranged from 4 to 20 mm Hg (15.5 ± 4.0 mm Hg).

In 19 patients, the noncompliant pattern disappeared during the hemodynamic monitoring period; its disappearance was not always accompanied by normalization of the mean right atrial pressure level. In seven patients we observed atrial pressure values equal to those of

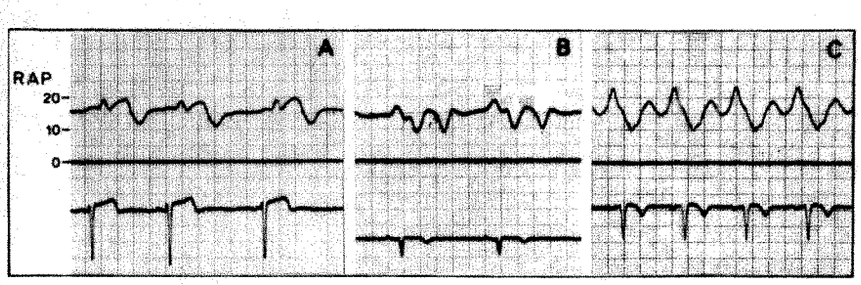

FIGURE 1. Right atrial pressure (RAP) (mm Hg) in three patients with a severe (**A**), a mild (**B**) and no (**C**) noncompliant pattern.

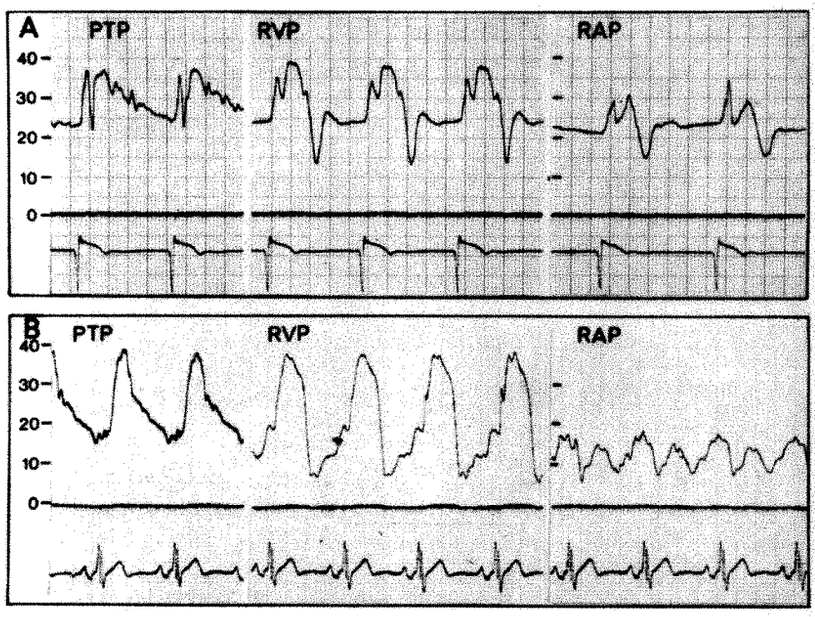

FIGURE 2. Pulmonary trunk (PTP), right ventricular (RVP) and right atrial (RAP) pressures (mm Hg) in two patients with a severe (**A**) and a mild (**B**) noncompliant pattern.

patients with the noncompliant pattern. The right ventricular pressure wave form on catheter withdrawal was normal in the 14 patients in whom a good quality recording was obtained.

Seven patients with a noncompliant pattern died in the coronary care unit with persistence of this pattern. Of the remaining 14 patients with a persistent noncompliant pattern at withdrawal, 13 had the severe form, and 1 the mild form. Right ventricular pressure was obtained in seven. Six who showed a severe noncompliant pattern had a protodiastolic dip greater than one third of the right ventricular pressure. In the other patient, the pattern was mild and the dip was less than one third (Fig. 2).

Jugular venous pulse: This recording revealed in all patients a pattern similar to that of the right atrial pressure wave form. The recording was very sensitive in differentiating patients with from those without the noncompliant pattern (Fig. 3). We therefore recorded the jugular venous pulse in the succeeding follow-up of survivors in order to assess the noncompliant pattern. Between 1 and 18 months after acute myocardial infarction, the jugular venous pulse was recorded in 9 of the 14 patients in whom the noncompliant pattern persisted throughout the entire period of hemodynamic monitoring. In seven of the nine, the jugular venous pulse was normal. In the remaining two patients, the noncompliant pattern was still present after 10 and 18 months, respectively. Both patients were asymptomatic and had elevated venous pressure as the only sign of right heart failure.

Respiratory recording: In 15 patients, respiration was recorded simultaneously with the right atrial pressure. The noncompliant pattern was severe in seven, mild in five and was not present in three. In no patient

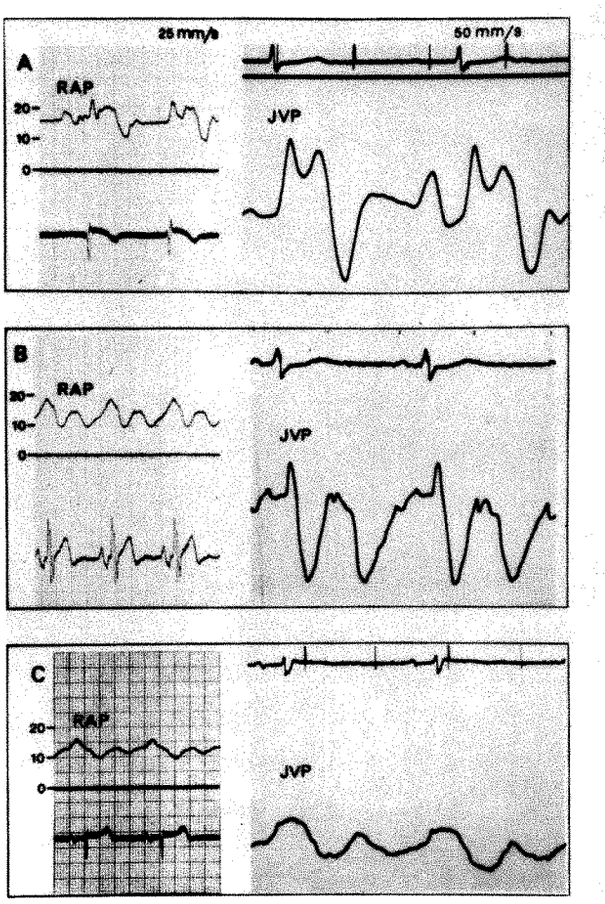

FIGURE 3. Right atrial pressure (RAP) (mm Hg) and jugular venous pulse (JVP) in three patients with a severe (**A**), a mild (**B**) and no (**C**) noncompliant pattern. Note the nearly identical shape of the right atrial pressure and jugular venous pulse curves in each case.

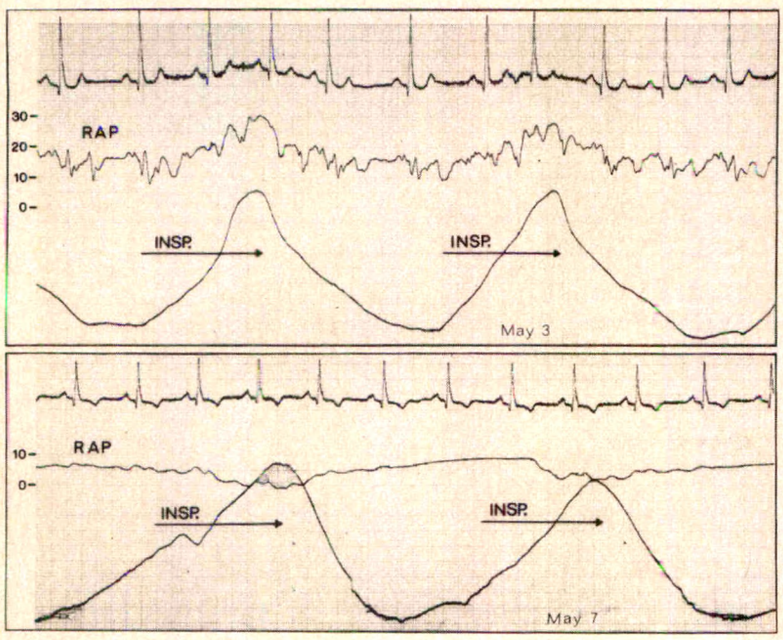

FIGURE 4. Right atrial pressure (RAP) (mm Hg) and respiration recordings in the same patient, the first (**top**) with a mild noncompliant pattern, in which the right atrial pressure increases in inspiration (INSP.), and later (**bottom**) after the noncompliant pattern has disappeared, with normal respiratory behavior.

did the right atrial pressure decrease with inspiration; it increased in 10 and did not change in 5, without any relation to the presence or severity of the noncompliant pattern. Two patients with a noncompliant pattern and an increase in right atrial pressure during inspiration had normal behavior when the noncompliant pattern was no longer present. In one of them, right atrial pressure was still elevated, and the other had a normal pressure (Fig. 4). One patient in whom the diagnosis of right ventricular dysfunction was made after volume overloading showed in basal conditions a 7 mm Hg right atrial pressure with a normal wave form and inspiratory increase (Fig. 5).

Low output syndrome: This syndrome was present in 32 (59 percent) of the 54 patients, occurring in 24 of the 30 patients with the severe form of noncompliant, in 4 of the 10 with the mild form and in 4 of the 14 without a noncompliant pattern. A significant relation was found between the severe form of noncompliant pattern and the low output syndrome ($p < 0.01$).

Mortality: Thirteen patients with the diagnosis of right ventricular dysfunction died before leaving the hospital. Postmortem study was performed in nine (Table II). All nine had acute necrosis in the posterior wall of the left ventricle, interventricular septum and right ventricle. Unfortunately, no quantitative analysis of the necrotic area was performed. We can only show the location of the necrosis, studied with incubation in triphenyl tetrazolium chloride solution and histologic examination. Severe coronary obstructive lesions (75 to 100 percent narrowing of luminal diameter) were observed in the dominant right coronary artery in all the

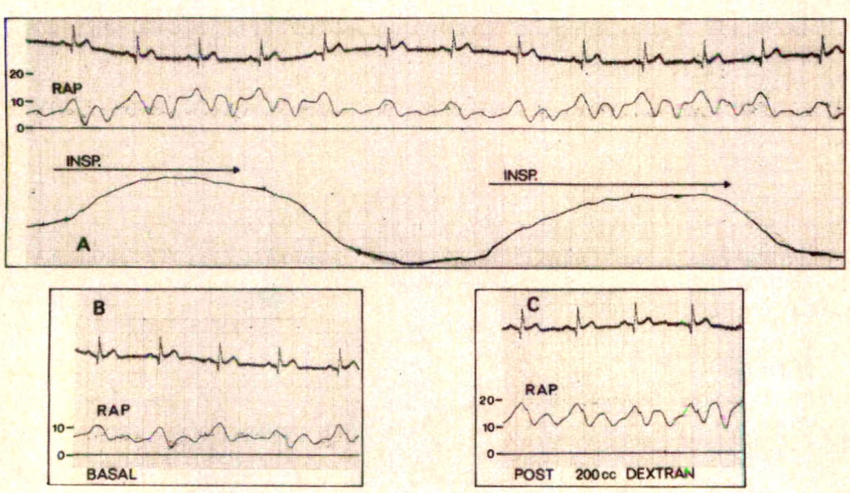

FIGURE 5. A, right atrial pressure (RAP) (mm Hg) in basal conditions. There is an increase during inspiration (INSP.). **B** and **C**, right atrial pressure in the same patient during apnea before (**B**) and after (**C**) volume overloading with 200 cc of dextran. The noncompliant pattern appears during inspiration (**A**) and later with volume overloading (**C**).

TABLE II

Postmortem Findings and Hemodynamic Pattern in Nine Patients With Right Ventricular Dysfunction

Case	Myocardial Infarction			Myocardial Rupture	Pulmonary Embolism	Pulmonary Edema	Coronary Obstructive Lesions (>75%)	Noncompliant Pattern
	RV	IVS	LV

29	P	P	P	No	No	No	RCA	Severe
37	P + AL	P	P + A	No	No	No	RCA + LAD	Severe
39	P	P + A	P + Ap + PPM	No	No	Yes	RCA + LAD + LCx	Absent

A = anterior; AL = anterolateral; Ap = apical; IVS = interventricular septum; LAD = left anterior descending coronary artery; LCx = left circumflex coronary artery; LV = left ventricle; LVPW = left ventricular posterior wall; RCA = right coronary artery; RV = right ventricle; P = posterior; PPM = posterior papillary muscle.

patients. Additional lesions in the left coronary tree are listed in Table II.

In five patients myocardial rupture or pulmonary embolism occurred suddenly while they were clinically asymptomatic. Seven patients died with a severe low output syndrome and their deaths were significantly related to the presence of the severe noncompliant pattern ($p < 0.05$): six had the severe form and one a normal wave form in the right atrial pressure tracing. The remaining patient (Case 39) died with acute pulmonary edema.

Discussion

In hemodynamic studies performed in patients with right ventricular dysfunction secondary to right ventricular infarction, slight attention has been paid to the significance of the pressure wave form of the right heart chambers. These wave forms have characteristics similar to those of constrictive pericarditis, with a dip plateau in the diastolic pressure of the right ventricle[20–25] and marked *x* and *y* descents in the right atrium.[21,22,25] This finding has been called "adiastolic syndrome" [21] or "pattern resembling pericardial constriction." [23] Earlier we had called it "restrictive pattern" [25] because of its similarities with that found in restrictive cardiomyopathy and because we believe it represents a difficulty in the expansion of the necrotic myocardium. We now use the term "noncompliant pattern," which we believe may be more appropriate and accurate.

Incidence: The incidence of this pattern is very high; we have found it in 74 percent of cases of ischemic right ventricular dysfunction. Although it is not an exclusive feature of ischemic right ventricular dysfunction, and by itself does not justify this diagnosis, the finding of a noncompliant pattern during acute myocardial infarction supports the diagnosis of ischemic right ventricular dysfunction. In fact, when it is present, the diagnosis of right ventricular infarction should be strongly suspected.

Similiarity to constrictive pericarditis and cardiac tamponade: In all of our cases in which respiration was recorded, the respiratory behavior was abnormal because the right atrial pressure did not vary or even increased during inspiration; this behavior was the same as that described by Lorell et al.[22] in two of seven cases, and by Jensen et al.[23] in their two cases of right ventricular infarction. The increase of pressure during inspiration, called Kussmaul's sign, has been described in constrictive pericarditis but only in its severe degree; in typical constrictive pericarditis there are no respiratory changes in right atrial pressure.[28,29] In cardiac tamponade, another situation with impaired cardiac filling and elevated right atrial pressure, inspiration is accompanied by a normal decrease in right atrial pressure and increase in velocity of flow in the superior vena cava, with absent Kussmaul's sign.[29] We have found Kussmaul's sign even in cases with a normal wave form and with only slightly elevated pressure in the right atrium (Fig. 5), which makes the interpretation of this finding difficult.

Causes of noncompliant pattern: The noncompliant pattern could be due to the increase in right ventricular diastolic pressure because ventricular compliance diminishes when filling pressure increases.[30] Furthermore, it has been postulated[31] that massive acute dilatation of one ventricle is prevented by the noncompliant pericardium, which limits its dilatation to the reserve volume of the pericardium.[31] However, in some cases we found a noncompliant pattern with normal or only slightly increased right atrial pressure, which proves there was a component of augmented myocardial stiffness.

Prognosis: The duration of the noncompliant pattern was extremely variable in our patients. Although in the majority it lasted less than a week (as in all the cases of Daubert et al.[21]), in a considerable number of patients it lasted longer, and even persisted for 10 months and 18 months, respectively, in two patients. Probably only the most severe cases of alteration of compliance show a noncompliant pattern, and the right ventricle has a greater degree of stiffness in the first few days after the infarction than in later stages. Diamond and Forrester[32] calculated a quantitative index of left ventricular stiffness called passive elastic modulus that

can also be applied to the right ventricle. We did not calculate this index because serial right ventricular pressures were not available. Nevertheless, we believe that the presence of a noncompliant pattern and the classifications severe and mild are very useful for the qualitative assessment of right ventricular compliance and the patient's prognosis.

Relation with low output syndrome: There was a clear relation between the presence of a noncompliant pattern and the clinical severity and mortality due to the low output syndrome; however, the longer persistence of this pattern did not indicate a poorer course: All the patients were asymptomatic once they were past the acute phase of the infarction. Considering that the most frequent clinical manifestation of ischemic right ventricular dysfunction is the low output syndrome, we compared the presence of a noncompliant pattern with the incidence of this syndrome, and found that the severe pattern is statistically related with it ($p < 0.01$). We also found a significant relation between the presence of a severe noncompliant pattern and mortality due to the low output syndrome ($p < 0.05$). Therefore we believe that the severe noncompliant pattern indicates a poor prognosis, as a result of a more severe degree of right ventricular stiffness. We cannot draw conclusive statements from the autopsy data because there was no quantitative assessment of the necrotic area, but it is reasonable to assume that the degree of dysfunction of the right ventricle, as of the left, is related to the extension of necrosis in the affected ventricle.

Diagnosis of right ventricular infarction: Gomez et al.[20] also found that a dip plateau in right ventricular pressure was a characteristic feature of right ventricular infarction in a group of six patients, as did Lorell et al.[22] in five of seven patients. Jensen et al.[23] found it in their two cases, Flammang et al.[24] in one and Daubert et al.[21] found it in all cases of a large series of posterior infarction, whereas infarction of the anterior wall of the right ventricle never produced this hemodynamic pattern. They therefore concluded that in posterior wall infarction absence of the "adiastolic syndrome" excludes right ventricular involvement.

In an earlier study done by our group[25] of 10 patients with right ventricular posterior infarction and severe low output syndrome all 10 had a noncompliant pattern. In the present series of 54 cases, right ventricular dysfunction was always associated with posterior necrosis of the left ventricle, and probably all 54 had right ventricular posterior infarction, but not all had a noncompliant pattern. We can therefore state that the noncompliant pattern is frequent in right ventricular infarction, but its absence does not exclude this diagnosis. In fact, among the five patients who died with a normal right atrial pressure wave form, in whom the diagnosis of right ventricular dysfunction was made according to our criteria, autopsy was performed in four, and necrosis of the posterior wall of the right ventricle was proved in all four. In every case of ischemic right ventricular dysfunction in which postmortem study was performed, right ventricular necrosis was present. However, we did find two patients, not included in this series, with anatomic involvement of the right ventricle and previously normal pressures. This finding supports the hypothesis that right ventricular necrosis in human beings is not necessarily accompanied by right ventricular dysfunction, as occurs with left ventricular necrosis, which is not uniformly accompanied by dysfunction of the left ventricle.

In clinical studies, the diagnosis of right ventricular infarction is made in light of elevated right ventricular filling pressure, reduced radionuclide right ventricular ejection fraction and an increased echographic right ventricular size, as well as accumulation of pyrophosphate in the right ventricle. According to these criteria the diagnosis of right ventricular infarction is made solely when right ventricular dysfunction is present. This may explain the difference between the clinical[33] and anatomic[19,34] incidence of right ventricular infarction. We believe that our criteria for the diagnosis of right ventricular dysfunction can be useful in detecting this condition in a greater number of cases.

Implications: Although it is well known that the jugular venous pulse tracing has a pattern quite similar to that of the right atrial pressure recording and is widely used in the assessment of right heart lesions,[35] we believe that this is the first report to describe the utility of this recording in evaluating normal or abnormal right ventricular compliance (Fig. 3) in the acute phase and follow-up periods of ischemic right ventricular dysfunction. It is a simple and useful noninvasive method that, in a large proportion of cases, can assist in the diagnosis of right ventricular dysfunction and in the prediction of prognosis of these patients.

Negative Intraventricular Diastolic Pressure in Patients With Mitral Stenosis: Evidence of Left Ventricular Diastolic Suction

HANI N. SABBAH
DANIEL T. ANBE, MD, FACC
PAUL D. STEIN, MD, FACC

Detroit, Michigan

Left ventricular diastolic pressure was evaluated in 15 patients with mitral stenosis and 16 patients with no significant heart disease to determine if a stenotic mitral valve can cause the left ventricle to produce a negative diastolic pressure, indicative of ventricular diastolic suction. The minimal level of diastolic pressure in patients with mitral stenosis ranged between 6 and −7 mm Hg; in normal subjects it did not fall below 0. The average value of minimal diastolic pressure in patients with mitral stenosis (−2 ± 1 mm Hg [mean ± standard error of the mean]) was significantly lower than in patients without significant heart disease (5 ± 1 mm Hg) ($p < 0.001$). These observations indicate that the human left ventricle, in the presence of mitral stenosis, can generate a negative diastolic pressure. The presence of a negative diastolic pressure in patients with mitral stenosis suggests that the dynamics of the ventricle during diastole may contribute to the filling process.

The concept of "left ventricular diastolic suction" has been debated for many years.[1] The question of whether the human ventricle can create a negative pressure during diastole, indicating a suction-like action, remains a controversial subject. If ventricular diastolic suction exists, the implication is that left ventricular filling in early diastole may be assisted by a process of active ventricular relaxation.[2–4] In general, it is thought that the ventricle is filled only by the pressure in the atrium during diastole and by atrial contraction, and diastolic pressure-volume relations are based on this assumption.[5–7]

A recent report[8] of a patient studied at autopsy has demonstrated that the human left ventricle has the capacity under certain circumstances to create a negative pressure during diastole, and this report renews interest in this subject. Several experimental studies[4,9–14] have demonstrated negative pressures within the left ventricle of animals. In particular, strong negative pressures were shown in dogs[12–14] and isolated dog hearts[4] when mitral inflow was impeded. These procedures were based on the premise that with a fully open mitral valve orifice, negative diastolic transmural pressures cannot be detected in the ventricle because the adjoining atrium has collapsible walls.[4] However, during occlusion of the mitral orifice, negative intraventricular pressure can be recorded. In view of these observations, if diastolic ventricular suction were present, one would expect to observe a negative intraventricular pressure in patients with mitral stenosis. In this study we evaluated left ventricular pressures during diastole in patients with mitral stenosis and compared them with diastolic pressure measurements in patients with no apparent heart disease.

Methods

Patients: Intraventricular pressure and sound were measured in 31 patients undergoing diagnotic cardiac catheterization. Fifteen patients had hemodynamic evidence of mitral stenosis and 16 had no abnormal hemodynamic or arteriographic findings. The patients with mitral stenosis had a mean diastolic pressure gradient across the mitral valve of 7 to 27 mm Hg. Among the 15 patients with mitral stenosis, 4 had no mitral regurgitation, 5 had ventriculographic evidence of mild to moderate mitral regurgitation, and 5 had severe mitral regurgitation. Three of these 15 patients had mild to moderate aortic insufficiency and one had a 70 percent narrowing of luminal diameter of the left circumflex coronary artery. Each of the 16 patients with a normal hemodynamic status were studied because of angina-like symptoms. One patient had mild mitral valve prolapse. None of these patients had arteriographic evidence of coronary artery disease.

Pressure and sound recordings: Pressure was measured with a catheter-tip micromanometer (Millar Instruments, Houston, Texas). The pressure-sensing element is an ultraminiature silicone strain gauge semiconductor designed specifically for catheter-tip applications. The transducer has a high signal to noise ratio and good resolution at low pressures because it provides an output several times higher than that of conventional external transducers. Its low mass makes it insensitive to acceleration forces and "catheter whip." The pressure sensor is a linear device with a normal output accuracy within 0.5 percent of any selected pressure range from −300 to +400 mm Hg. The sensor has a frequency response of 0 to 20 kilohertz and a natural frequency of 25 to 40 kilohertz. The phase lag of this type of sensor is 90° at 35 kilohertz, which is equivalent to a time delay of approximately 7 μs. Tests in our laboratory showed a baseline drift of less than 1 mm Hg in 3 hours. The zero baseline of the transducer was adjusted to atmospheric pressure at the beginning of each procedure. In view of baseline shifts that may occur with temperature differences between the body and room air, the level of zero pressure was reestablished after withdrawal of the catheter-tip micromanometer from the brachial artery (Fig. 1). In some patients, sound within the left ventricle was recorded simultaneously with pressure, with use of the same transducer. Recordings of pressure and sound were obtained on a VR-6 photographic recorder (Electronics for Medicine) at speeds of 25 to 200 mm/s. The frequency response of the recording system was flat to 700 hertz with a 3 decibel drop at 2,100 hertz. However, pressures were filtered at frequencies above 250 hertz.

Left ventricular pressure during diastole was measured at the lowest point that the pressure reached during the filling period. In almost all instances this occurred during the rapid phase of filling. The measurements in each patient were averaged over 15 to 20 consecutive cardiac cycles. Premature ventricular contractions and postextrasystolic beats were excluded from these measurements.

Ventriculograms in the right anterior oblique projection were obtained on 35 mm cine film in 25 of 31 patients. Left ventricular end-systolic and end-diastolic volumes were calculated with the single plane area-length method. Amplification was determined by utilization of a two dimensional scale that also permitted compensation for any roentgenographic distortion. Such distortion was negligible.

Pulmonary arterial pressure and pulmonary wedge pressure were measured using fluid-filled catheters attached to a P23ID pressure transducer (Gould Statham Inc., Hato Rey, Puerto Rico).

Results

Patients with mitral stenosis: In this group, minimal diastolic pressure was −2 ± 1 mm Hg (Table I) (Fig. 2 to 4). In 10 of 15 patients, a negative intraventricular pressure during diastole was recorded. In three patients, minimal diastolic pressure was zero, and in two patients it was positive. The two patients whose minimal diastolic pressure remained positive had only mild to moderate mitral stenosis: The mitral valve area in one was 1.7 cm^2; in the other, it was 1.3 cm^2, excluding corrections for severe mitral regurgitation. In the patients in whom a negative diastolic pressure was recorded, the maximal negative pressure occurred during the rapid phase of left ventricular filling. The minimal diastolic pressure, particularly in patients with atrial fibrillation, varied in magnitude from beat to beat.

Patients without significant heart disease: In this group, the minimal pressure reached during diastole ranged from 1 to 11 mm Hg (5 ± 1 mm Hg) (Table I, Fig. 5 and 6). As in the patients with mitral stenosis, the lowest pressure during diastole was reached during the rapid phase of left ventricular filling. Minimal ventricular diastolic pressure was significantly higher in the patients without significant heart disease than in the patients with mitral stenosis ($p < 0.001$, unpaired t test).

Left ventricular end-systolic volume in patients with mitral stenosis (59 ± 9 cm^3) was not significantly dif-

ferent from that of the normal group (39 ± 7 cm^3). Hemodynamic measurements in both groups of patients are shown in Table I.

Discussion

Our results indicate that the human left ventricle can create a negative diastolic pressure, thereby creating ventricular diastolic suction under certain circumstances. The presence of a reduced inflow orifice, as a result of severe mitral stenosis, allowed a negative diastolic pressure to occur during left ventricular filling. To our knowledge, this is the first time that such a hemodynamic observation has been made in human beings. In the group of patients with no significant heart

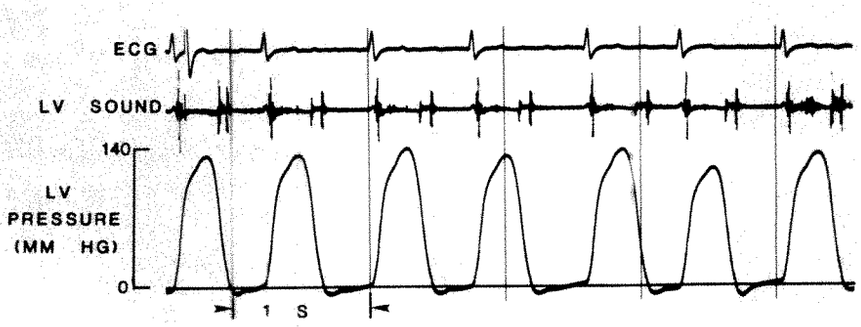

FIGURE 2. Patient 3, mitral stenosis. Left ventricular (LV) pressure and intraventricular sound recordings. A negative ventricular diastolic pressure is apparent. The intracardiac sound tracing shows a mitral opening snap. ECG = electrocardiogram.

disease, a negative diastolic pressure was not observed during left ventricular filling.

Previous observations: Observations similar to those made in this study have been made in animals. In 1956, Brecher[4] recorded negative diastolic pressures in the intact dog heart of −1.3 to −10.8 cm H_2O, when the mitral orifice was temporarily occluded. Others[12–14] subsequently showed similar results. Fowler et al.[14] produced left ventricular inflow obstruction by inflation of a Foley catheter inserted through the left atrial appendage. Obstruction of mitral inflow resulted in negative left ventricular diastolic pressures of −2.5 to −18 mm Hg. The magnitude of negative pressures observed in our study are within the range observed by these investigators.

Rapid bleeding from the right ventricle also resulted in negative left ventricular diastolic pressures (−2.5 to −6.5 mm Hg).[14] An autopsy report by Roberts et al.[8] of a man who died after a gunshot wound seemed to reflect this mechanism. A bullet entered the right atrium and exited from the right ventricle. The left atrial appendage was invaginated through the mitral orifice. According to their interpretation, the left ventricle, after emptying its chambers and the blood in the lungs, created a sucking action sufficiently strong to cause the left atrial appendage to invaginate and be "pulled" through the mitral orifice toward the left ventricle. This appeared to substantiate the creation of negative diastolic pressure by the human left ventricle.

Several investigators[8,9,14,15] have suggested that a negative diastolic pressure occurs in the left ventricle only when the end-systolic volume is small. In our study, no significant difference was observed between the end-systolic volume of patients with mitral stenosis and patients with a normal heart. The negative diastolic pressure we observed in patients with mitral stenosis appears to be related to the maintenance of a vigorous contraction in the presence of severe valve stenosis. The ventricles appear to have exerted a vigorous sucking action to draw blood through the reduced inflow orifice.

Implications related to mechanisms of ventricular filling: Our observations and those made by others regarding the capability of the mammalian left ventricle to create, under certain circumstances, a negative diastolic pressure have implications related to the mechanism of left ventricular filling. Current concepts indicate that left ventricular filling is due to the atrioventricular pressure gradient and atrial contraction. In contradistinction, the measurement of negative pressure in the ventricle during diastole suggests the possible presence of an alternate or perhaps a complementary mechanism, possibly that of an "active" diastole. Rushmer et al.[2] suggested that during systole the myocardial fibers in different layers must pull against each other and apply stretch to the connections between them and that this action represents potential energy that is wasted so far as systolic ejection is concerned. However, as the ventricles begin to relax, this potential energy would be released and could act to return the ventricular chambers to their original diastolic dimen-

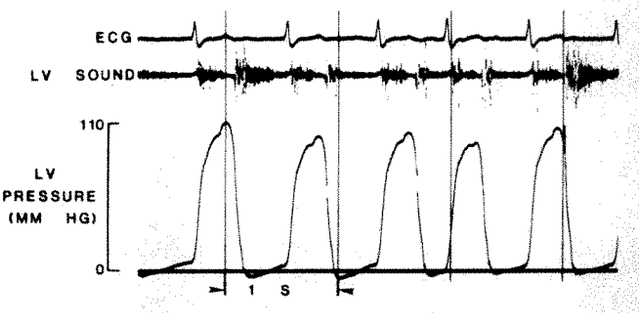

FIGURE 3. Patient 8, mitral stenosis. Left ventricular (LV) pressure and intraventricular sound recordings. The magnitude of the negative diastolic pressure varies from beat to beat. Atrial fibrillation is present. A diastolic murmur is recorded within the left ventricle.

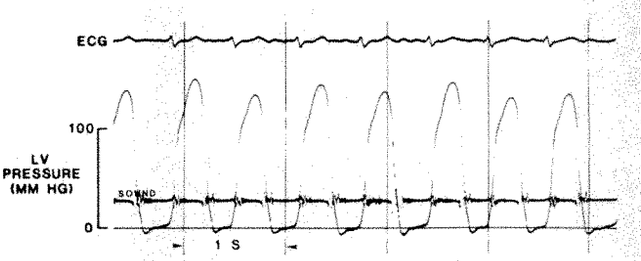

FIGURE 4. Patient 11, mitral stenosis. Left ventricular (LV) pressure and sound recordings. In some beats, negative left ventricular diastolic pressure is maintained throughout diastole. ECG = electrocardiogram.

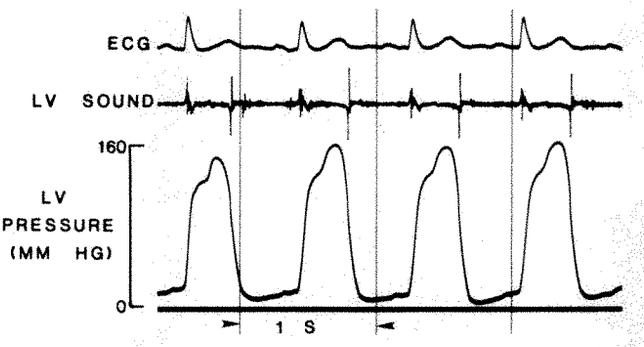

FIGURE 5. Patient 4, normal group. Left ventricular (LV) pressure and sound recordings. The pressure is positive throughout diastole. ECG = electrocardiogram.

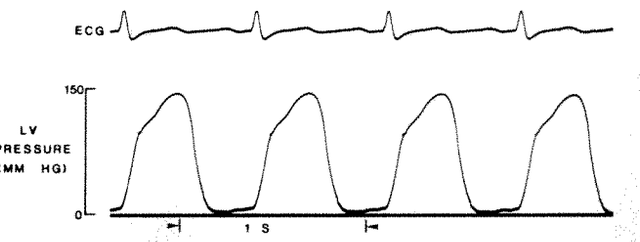

FIGURE 6. Patient 1, normal group. Left ventricular (LV) pressure recording. Diastolic pressure does not fall below zero. ECG = electrocardiogram.

sions. Therefore, the inflowing blood would encounter a small resistance to distension and thus facilitate rapid filling in early diastole. It was suggested[2] that such an effect should not be termed a "suction" unless the intraventricular pressure drops below the pressure immediately outside the walls. Others[15] have suggested that elastic forces (elastic recoil) tend to restore ventricular diastolic dimensions under stable conditions and that such forces are in part responsible for ventricular suction. Other mechanisms, including the possibility that some parts of the heart muscle contract during diastole and thereby assist in expansion of the ventricle as a whole, have also been proposed.[16]

In conclusion, the human left ventricle, in the presence of mitral stenosis, can generate a negative diastolic pressure. Presumably, diastolic function is similar in normal subjects, but a negative diastolic pressure does not develop because ventricular inflow is unimpaired (a partial vacuum cannot form). The presence of a negative diastolic pressure in patients with mitral stenosis suggests that dynamics of the ventricle during diastole may participate in the filling process.

Echocardiography in Assessing Acute Pulmonary Hypertension Due to Pulmonary Embolism

WOLFGANG KASPER, MD
THOMAS MEINERTZ, MD
FRIEDRICH KERSTING, MD
HERBERT LÖLLGEN, MD
PETER LIMBOURG, MD
HANJÖRG JUST, MD

Mainz, West Germany

Eighteen patients with acute pulmonary embolism were studied with right heart catheterization and M mode echocardiography. No patient had evidence of preexisting cardiopulmonary disease; pulmonary embolism was documented with pulmonary angiography. The mean pulmonary arterial pressure correlated with the angiographic severity index of embolic obstruction ($r = 0.61$, $p < 0.001$). The size of the right pulmonary artery was evaluated with suprasternal echocardiography and corrected for body surface area (index size). In patients with elevated mean pulmonary arterial pressure (greater than 20 mm Hg) the index size was increased (mean ± standard error of the mean 15.1 ± 0.6 mm/m², $p < 0.001$) over values in a control group of 25 normal subjects with a mean normal pulmonary arterial pressure (9.6 ± 0.9 mm/m²) and in 5 patients with acute pulmonary embolism and a mean normal pulmonary arterial pressure (10.9 ± 0.4 mm/m²). For all measurements the index size of the right pulmonary artery correlated with the mean pulmonary arterial pressure ($r = 0.84$, $p < 0.001$). Precordial echocardiography revealed that the right ventricular dimension was increased in 13 of 16 patients and the left ventricular dimension decreased in 10 of 15 patients. Thus, the right ventricular end-diastolic/left ventricular end-diastolic ratio was above normal in 14 of 15 patients when compared with the value in 25 normal subjects. This ratio correlated well with the angiographic severity index of embolic obstruction ($r = 0.83$, $p < 0.001$). The E-F slope of the anterior mitral leaflet was reduced in 12 of 16 patients. In eight patients an abnormal pattern of septal motion was observed, exhibiting a posterior motion during diastole. Suprasternal and precordial echocardiography seems to be a valuable noninvasive technique in the assessment of acute pulmonary hypertension in patients with acute pulmonary embolism with no known prior cardiopulmonary disorder.

Once massive pulmonary embolism has occurred, mean pulmonary arterial pressure is increased in almost all patients.[1,2] In those free of prior cardiopulmonary disease the elevation of the pulmonary pressure is related to the degree of pulmonary embolic obstruction.[3] In a wide number of experimental,[4,5] radiologic[6–8] and clinical investigations,[2] it has been shown that the right ventricle and the pulmonary arteries become dilated during acute pulmonary embolism, and that the variations in vessel size reflect the change in pulmonary arterial pressure.[9]

With suprasternal echocardiography, information on the size of the right pulmonary artery[10] can be obtained, and with the precordial approach the diameter changes of the right and left ventricular chambers can be evaluated. The echocardiographic features of chronic pulmonary hypertension are well known,[11,12] whereas those of acute pulmonary hypertension due to pulmonary embolism have not been studied. This study was undertaken to evaluate prospectively whether acute pulmonary hypertension can be detected by analysis of echocardiographic measurements in patients with acute pulmonary embolism.

Methods

Patients: Eighteen patients with acute pulmonary embolism were studied with echocardiography, right heart catheterization and pulmonary angiography. The pulmonary embolism was angiographically demonstrated in all. The patients had a mean age of 52 years. Only patients without evidence of prior cardiopulmonary disease were studied. Two patients (Cases 10 and 15) presented with the characteristic history of several embolic events recurring within 1 week. Because widening of the right pulmonary artery and alteration of the right ventricular end-diastolic left ventricular end-diastolic ratio can be expected in patients with a history of primary pulmonary hypertension, congenital heart disease or valvular heart disease and in those with symptoms of left ventricular failure, patients with these conditions were excluded from the study. The pulmonary embolism was related to a preceding operation in 13 patients and to a malignant neoplasm in 3; in 2 patients no underlying disease could be detected.

Echocardiography: Echocardiograms were obtained immediately before pulmonary angiography at least 18 hours after the acute embolic event. A Siemens Echopan KS ultrasonoscope with a nonfocused 2.25 megahertz transducer was used. Suprasternal notch echocardiograms were performed with the patients supine. By having the patient rotate his head counterclockwise, it was possible to position the transducer into the suprasternal notch below the level of the sternum. The right pulmonary artery shows a characteristic motion pattern in the suprasternal echocardiogram (Fig. 1). When the atrium contracts the superior wall of the left atrium separates from the inferior wall of the right pulmonary artery, thus forming a box like configuration. The atrial contraction produces an atrial dip in the wall motion of the right pulmonary artery. In addition, the superior wall of the right pulmonary artery moves parallel to and is somehow dampened in relation to the inferior wall. During isovolumic contraction the right pulmonary artery is shifted upward, showing a small notch (IC point) in its wall motion. The diameter at the level of the IC point was chosen as the reference point for the measurements of the size of the right pulmonary artery and represents its end-diastolic diameter. During systole the diameter of the right pulmonary artery increases with an increase in pulmonary arterial pressure. Because of slight variations in the position and in the size of the right pulmonary artery during breathing, its size was measured at end-expiration.

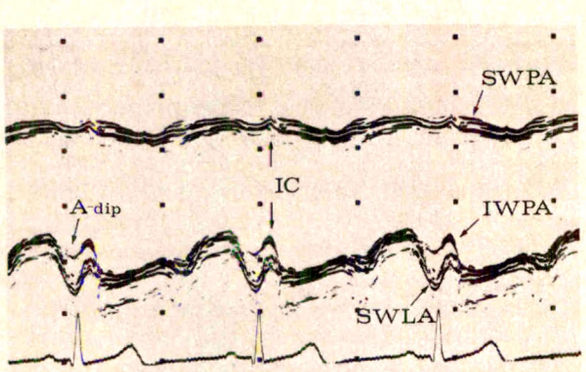

FIGURE 1. The normal right pulmonary artery shows a characteristic motion pattern during the cardiac cycle. The superior wall of the left atrium (SWLA) separates from the inferior wall of the right pulmonary artery (IWPA) during atrial contraction, producing the A dip. The superior wall of the right pulmonary artery (SWPA) moves parallel to and in slightly dampened fashion with respect to the inferior wall (IWPA). During isovolumic contraction the right pulmonary artery is shifted upward, producing a small notch (IC point) in its wall motion.

All the echocardiographic measurements were made independently by two investigators without knowledge of the angiographic data. The interobserver differences were below the 5 percent level for the size of the right pulmonary artery and below the 10 percent level for the echocardiographic measurements obtained with the precordial approach. Also, to minimize breathing-dependent and position-induced alterations of the right and left ventricular diameter, precordial echocardiograms were obtained in a standardized manner, that is, during end-expiration with the patients in a supine position.

The size of the right pulmonary artery and the right ventricular end-diastolic/left ventricular end-diastolic ratio were also measured in 25 normal subjects serving as controls. Subsequently, the size of the right pulmonary artery was corrected for body surface area, in the control and study groups because it has been shown that the size of this artery is related to the body surface area.[13] The motion of the interventricular septum was evaluated at the level of the mitral valve because an adequate echocardiogram below the level of the mitral valve could not be obtained in all patients.

Pulmonary angiography: Pulmonary angiograms were graded by one of us (P.L.) according to the objective angiographic severity index for pulmonary embolism,[14] without knowledge of the patients' history. This severity index is a semiquantitative grading system in which only angiographic abnormalities specific for pulmonary embolism such as filling defects and obstructions are considered. Depending on the degree of vessel obstruction a score was estimated within the range of 1 to 9. By general agreement obstruction of a segmental pulmonary artery was scored as 1, whereas obstruction of the main pulmonary artery was scored as 9. Filling defects were graded with respect to their anatomic location; for example, a filling defect in a segmental region was given a score of 1 and one in the central region a score of 3. By convention, the sum of the scores achieved in one lung should never exceed 9.

Results

The hemodynamic and echocardiographic data obtained in all patients are summarized in Table I. The size of the right pulmonary artery could be determined in each patient. The right ventricular end-diastolic diameter could not be determined in 2 and left ventricular end-diastolic diameter in 3 of 18 patients, and interventricular septal motion could not be assessed in one patient. The pulmonary valve could be recorded in only 2 of 18 patients (Cases 12 and 17); in both patients the pattern of valve motion was normal.

Correlation of size of right pulmonary artery and pulmonary pressures: The mean pulmonary arterial pressure (PAP_m) was elevated (greater than 20 mm Hg) in 13 of 18 patients. If Patients 10 and 15 are omitted (because of a recurrent embolic event) the increase in the mean pressure correlated with the angiographic severity index of pulmonary embolism ($r = 0.61$, $p < 0.001$). In each of the 13 patients with elevated pulmonary pressure the index size of the right pulmonary artery determined with suprasternal echocardiography was considerably greater (15.1 ± 0.6 mm/m^2, $p < 0.001$) than in the 5 patients with a normal mean pulmonary

ASIEO = angiographic severity index of embolic obstruction; E-F = E-F slope of echocardiogram (mm/sec); LV = left ventricular; LVEDD = left ventricular end-diastolic diameter (mm); PAP = pulmonary arterial pressure (mm Hg) (systolic/diastolic/mean); RPA = size of right pulmonary artery corrected for body surface area (mm/m^2); RV = right ventricular; RVEDD = right ventricular end-diastolic diameter (mm).

arterial pressure (10.9 ± 0.4 mm/m^2). The index size of the right pulmonary artery of these 13 patients was also greater in comparison with that of the control group of 25 normal patients (9.6 ± 0.9 mm/m^2). There existed a close correlation between index size of the right pulmonary artery and mean pulmonary arterial pressure ($r = 0.84$, $p < 0.001$) (Fig. 2). In six patients with elevated mean pulmonary pressure (Cases 1, 2, 4, 6, 8 and 11) right heart catheterization was repeated 2 to 6 weeks after treatment. In these patients normalization of the pulmonary pressure was associated with a reduction of the size of the right pulmonary artery to nearly normal (10.9 ± 0.4 mm/m^2) (Fig. 3).

Ventricular dimensions (Table I): During acute pulmonary embolism dilatation of the right ventricle was found in 13 of 16 patients whereas a small left ventricular end-diastolic diameter was found in 10 of 15 patients. Thus the ratio of right to left ventricular end-diastolic diameter in 15 patients with acute pulmonary embolism differed markedly (1.1 ± 0.32) from the ratio in 25 normal subjects (0.43 ± 0.1) ($p < 0.001$). This normal value for end-diastolic ratio is in excellent agreement with the normal reported range (0.13 to 0.62)[15] (Fig. 4).

A significant correlation was found when the right to left ventricular end-diastolic ratio was plotted against

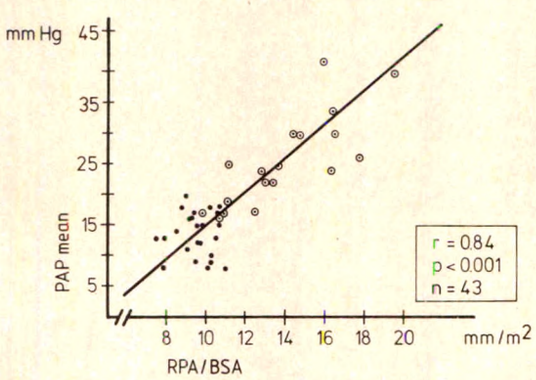

FIGURE 2. Correlation between index size of the right pulmonary artery (RPA/BSA) and mean pulmonary arterial pressure (PAP mean) in 18 patients during acute pulmonary embolism (**open circles with dots**) and in 25 normal subjects with normal mean pulmonary pressure (20 mm Hg or less) (**closed circles**). n = number of subjects; p = probability; r = correlation coefficient.

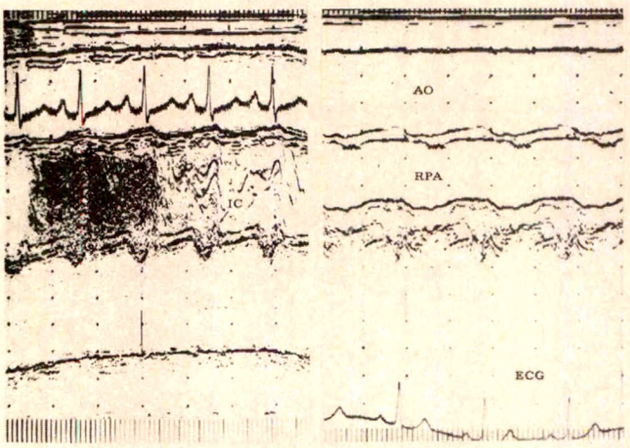

FIGURE 3. Case 1. Typical suprasternal echocardiogram during acute pulmonary embolism (**left panel**). Saline solution was injected, causing a shower of microbubbles within the lumen of the right pulmonary artery (RPA). The suprasternal echocardiogram on the right (**right panel**) was obtained 16 days later, after normalization of the pulmonary arterial pressure. Note the reduction in size of the right pulmonary artery from 30 to 20 mm. AO = aorta; ECG = electrocardiogram; other abbreviations as in Figure 1.

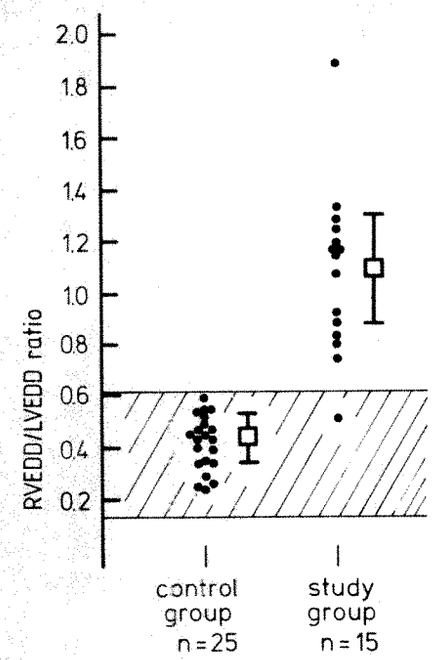

FIGURE 4. The ratio of right to left ventricular end-diastolic diameter (RVEDD/LVEDD) in patients with acute pulmonary hypertension (study group) (mean ± standard deviation 1.1 ± 0.32) differed markedly from that of the control group (0.43 ± 0.1) ($p < 0.001$). The **patched area** represents the reported normal range for this ratio.

the angiographic index of severity of embolic obstruction ($r = 0.83$, $p < 0.001$) (Fig. 5). The E-F slope of the anterior mitral leaflet was reduced in 12 of 16 patients when compared with normal values.[16] In 8 of 17 patients a paradoxic septal motion pattern was observed. In these patients the septum bulged posteriorly toward the left ventricular cavity during diastole (Fig. 6).

Discussion

Recently it has been shown that in patients without prior cardiopulmonary disease the elevation of the mean pulmonary arterial pressure is related to embolic obstruction. Several experimental and clinical studies have demonstrated that the main pulmonary artery dilates during acute pulmonary embolism and that this dilatation is due to the increase in pulmonary pressure. Dilatation of the main pulmonary arteries has also been described in previous studies using chest X-ray films and pulmonary angiography. However, the clinical significance of this radiologic sign has not been well established.

Echocardiographic size of right pulmonary artery and severity of pulmonary hypertension: With suprasternal echocardiography it is possible to measure the size of the right pulmonary artery easily and with accuracy. In our study the mean pulmonary arterial pressure correlated with the angiographic index of severity of embolic obstruction. However, the correlation was not as close as that observed by McIntyre and Sasahara.[3] This difference is possibly due to the smaller number of patients in our study as well as to differences in grading of pulmonary obstruction.

In 13 patients with acute pulmonary embolism the size of the right pulmonary artery was increased compared with that in the control group and correlated strikingly with the mean pulmonary arterial pressure, which was elevated in these patients. In six patients who underwent a second right heart catheterization after treatment, normalization of pulmonary arterial pressure was associated with a reduction in size of the right pulmonary artery to normal values. In the two patients whose pulmonary valve was visualized, a normal pattern of motion was found. The inability to record the pulmonary valve in 16 of 18 patients may have been due to the general technical difficulties of obtaining a rea-

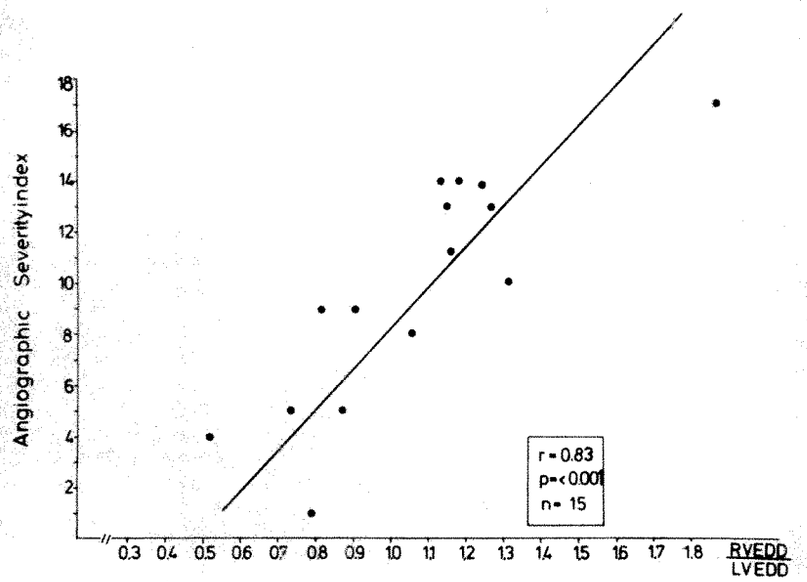

FIGURE 5. Ratio of right to left ventricular end-diastolic diameter (RVEDD/LVEDD) plotted against the angiographic index of severity of embolic obstruction.

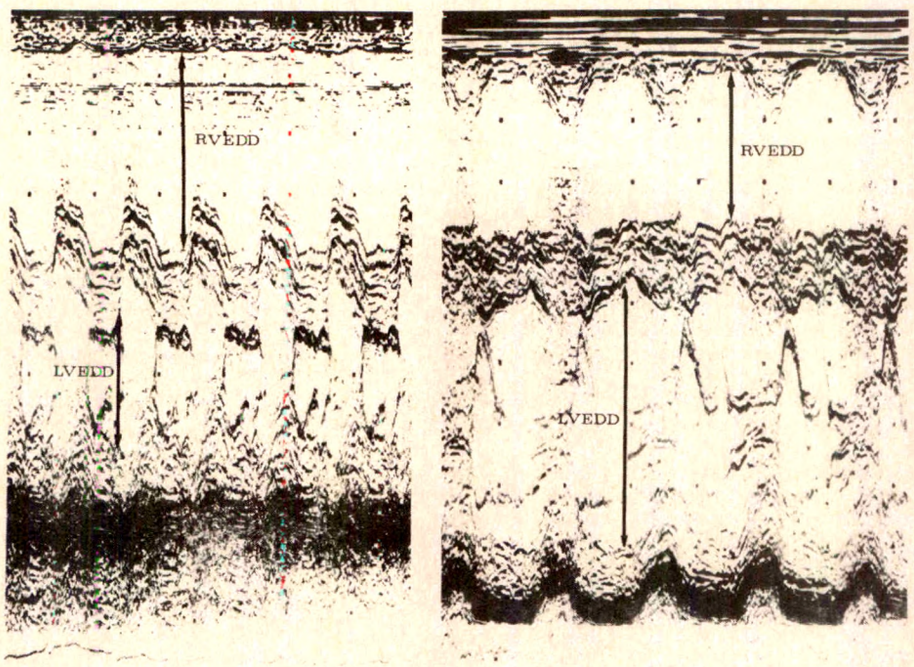

FIGURE 6. Case 9. This precordial echocardiogram is an impressive example of the massive hemodynamic alterations occurring during acute pulmonary embolism (**left panel**) and 14 days after successful treatment (**right panel**). Note the changes in end-diastolic diameter (EDD) of the right (RV) and left (LV) ventricular chambers. **At left,** the septum bulges toward the left ventricle during diastole, thus impeding left ventricular filling, as evidenced by the reduction of the E-F slope of the anterior mitral leaflet. **At right,** septal motion and E-F slope are normalized. In **the left panel,** the echographic record of the anterior wall of the right ventricle was retouched for demonstration purposes.

sonably good echocardiogram of this valve in patients with severe dyspnea or tachypnea.

Right ventricular hemodynamics: In some studies[17–19] using precordial echocardiography in patients with acute pulmonary embolism a reliable pattern for clinical assessment of this disease could not always be obtained. However, our study demonstrates that the precordial approach does yield valuable information about right and left ventricular hemodynamics during acute pulmonary embolism. It can be assumed that the increase in right ventricular dimension and the bulging septal motion toward the left ventricular cavity during diastole in the acute state of pulmonary embolism are due to acute right ventricular pressure stress. Similar findings were observed in animal studies[20] during acute pulmonary hypertension and in patients with chronic right ventricular pressure overload.[11,12,21]

Left ventricular hemodynamics: In addition, left ventricular hemodynamics were also affected in acute pulmonary hypertension. In most of the patients the reduction of the left ventricular end-diastolic diameter and the reduced E-F slope of the anterior mitral leaflet in 12 of 16 patients are echocardiographic indexes for the changes in left ventricular shape and compliance. These findings are indirectly supported by similar observations in animal studies during experimental acute pulmonary hypertension.[20] Patients with chronic pulmonary hypertension seem to react in a similar way.[21] Figure 6 demonstrates impairment of left ventricular filling which might be explained by the bulging of the interventricular septum posteriorly during acute right ventricular pressure overload. If this is true then left ventricular dysfunction (reversed Bernheim effect[22]) in conditions with right ventricular volume and pressure stress seems to be echocardiographically confirmed at least in some patients with acute pulmonary embolism.

Implications: Our results show that a dilated pulmonary artery, delineated by suprasternal echocardiography, indicates an increase in pulmonary arterial pressure and that the ratio of right to left ventricular end-diastolic diameter correlates well with the angiographic index of severity of embolic obstruction in patients with acute pulmonary embolism. The presence or absence of pulmonary hypertension in acute pulmonary embolism determines substantially further therapeutic steps. Thus in our opinion, suprasternal and precordial echocardiography is an important noninvasive technique in the assessment of acute pulmonary hypertension in patients with acute pulmonary embolism who have no history of prior cardiopulmonary disease.

Fourteen patients who had a left ventricular apex to abdominal aorta composite conduit implanted for relief of severe left ventricular outflow tract obstruction were studied at cardiac catheterization 7 days to 19 months postoperatively (median 12 days). Analysis of pressure, angiographic and blood flow velocity data showed the following: (1) The left ventricle to aorta pressure gradients were reduced from an average preoperative value of 100.6 mm Hg (range 54 to 140) to an average of 22.1 mm Hg (range 0 to 60) postoperatively; (2) postoperative left ventricular end-diastolic volume averaged 87.5 percent of normal (range 51 to 146); (3) cardiac index and ejection fraction were normal postoperatively in all but one patient. Left ventricular and aortic angiography revealed blood flow through both the ascending aorta and conduit in all patients and retrograde flow of blood from the conduit to the aortic arch in four. An average of 36 percent (range 16 to 50) of the left ventricular output was ejected through the conduit. It appears that this operation is effective in relieving severe and otherwise inoperable left ventricular outflow tract obstruction and in preserving or improving left ventricular function and aortic hemodynamics.

The interposition of a valved conduit from the apex of the left ventricle to the descending aorta has been applied recently to a number of patients who have had extensive or severe left ventricular outflow tract obstruction which cannot be relieved by other surgical techniques.[1–3] Both experimental[4,5] and clinical[6,7] reports indicate that the conduit relieves left ventricular outflow tract obstruction effectively for follow-up periods of as long as 4 to 13 years. The present studies were devised to evaluate left ventricular function and the conduit hemodynamics in 14 patients after surgical placement of an apical-aortic conduit.

Methods

Patients: Between August 1975 and August 1979, 28 patients underwent operation using a valved composite conduit placed from the apex of the left ventricle to the supraceliac abdominal aorta for relief of left ventricular outflow tract obstruction (Table I). This number represents 1.54 percent of all patients having operations for various forms of aortic stenosis at this institution during this period. The age of the patients ranged from 5 to 72 years; 10 were less than 10 years. Eleven were female and 17 male.

Thirteen of the 25 survivors underwent cardiac catheterization 7 days to 19 months postoperatively (median 12 days). One patient operated on elsewhere by a similar technique also had a catheterization at Texas Children's Hospital 6 months postoperatively and is included in this report. Nine of these patients were male and five female; they ranged in age from 9 to 72 years.

Operation: The operative technique has been described elsewhere.[6,7] Briefly, all patients except one were operated on with use of cardiopulmonary bypass and moderate systemic hypothermia (30° C). Starting in April 1977, cold cardioplegic solution was infused into the aortic root for myocardial preservation.

This solution was used in only one patient undergoing postoperative catheterization. A Dacron® conduit is anastomosed to the apex of the left ventricle after removal of a plug of myocardium. The conduit is passed through an aperture made in the diaphragm adjacent to the apex and anastomosed to a valved conduit whose distal end has been anastomosed to the supraceliac abdominal aorta. The conduit contains a porcine xenograft valve (Hancock Laboratories, Inc., Anaheim, California).

The Dacron conduit was anastomosed directly to a circular opening in the left ventricular apex in the first four patients operated on; in the others, a rigid Pyrolite® (Texas Technology Transfer Laboratories, Inc., Houston, Texas) or soft Hancock® (Hancock Laboratories, Inc., Anaheim, California) left ventricular apex outlet prosthesis, with an attached sewing ring, was inserted into the distal left ventricular cavity (Table I).

Catheterization: Patients less than 15 years of age were sedated with meperidine hydrochloride, 1.5 mg/kg; promethazine hydrochloride, 0.2 mg/kg; and chlorpromazine, 0.25 mg/kg. The older patients received either diazepam, 10 mg intramuscularly, or no sedation. Cardiac catheterization was performed by the percutaneous sheath technique from the femoral artery and vein.[8] Right as well as left heart catheterization was performed in all patients and cardiac output was determined with the indocyanine green method in seven patients. The left ventricle was entered by transseptal atrial puncture in two patients, retrograde by way of the aortic valve in six, retrograde by way of conduit in four and by way of both the aortic valve and conduit in two patients. The pressure gradient between the left ventricle and mid thoracic aorta was measured in the resting subject before angiography was performed.

Biplane left ventricular cineangiography was performed in five patients, all children, in both anteroposterior and lateral projections and in the 30° right anterior oblique and left anterior oblique projections. In the other nine patients, single plane left ventricular angiography was performed in the 30° right anterior oblique projection. The amount of contrast material used for left ventricular angiography in the adolescents and adults ranged from 40 to 50 cc; in the children 1.25 cc/kg body weight was used per injection.

Left ventricular volumes were calculated from end-diastolic and end-systolic frames traced from the right anterior oblique projection using the single plane area-length method of Kennedy et al.[9] Left ventricular ejection time (LVET) and heart rate were calculated by counting the cine frames from end-diastole (the frame with the largest area) to end-systole (the frame with the smallest area). The longest length was measured from the inferior aortic anulus to the mid apex at the junction of the conduit and endocardium. End-diastolic volume (EDV), ejection fraction, stroke index and cardiac index were calculated.[10,11] Mean velocity of circumferential fiber shortening was calculated from the normalized shortening of the calculated minor axis divided by the ejection time

(EDD − ESD)/EDD ÷ LVET = circumferences/s),[12,13] where EDD and ESD are end-diastolic and end-systolic diameter, respectively. Mean systolic ejection rate was calculated from the ejection fraction divided by left ventricular ejection time (EDV − ESV)/EDV ÷ LVET,[12,13] where EDV and ESV are end-diastolic and end-systolic volume, respectively. Left ventricular cavity obliteration at end-systole[14] was expressed as percent of end-diastolic length.

A visual estimate of the percent of left ventricular output passing through the conduit during angiography was made by an observer without knowledge of the calculated conduit flows. The position of the catheter during angiography was noted.

Angiograms also were taken in the ascending aorta in 10 patients and in the mid or lower thoracic aorta in 9. The aortic internal diameter was measured 2 cm above and below the distal conduit anastomosis, and the conduit internal diameter was measured midway between the porcine valve and the distal anastomosis. Magnification was corrected for by measuring a 1 cm^2 grid filmed in the position of the left ventricle in the right anterior oblique position.

Velocity measurements: A catheter-tip velocity probe[15] (Carolina Medical Electronics, North Carolina and Millar Instruments, Houston, Texas) coupled to a square wave electromagnetic flow meter (Carolina Medical Electronics) was passed in retrograde manner from the femoral artery; velocity tracings were unsuitable for measurement in one patient because of excessive electric noise. The polarity of the velocity catheter was set so that a positive deflection was recorded when blood flowed toward the catheter tip. At end-diastole there was a stable baseline that represented zero flow, and any negative deflection below this baseline represented reversed flow away from the catheter tip. The velocity cathethers had been calibrated previously by determining the probe factor at which the mean velocity was equal to the calculated velocity over a range of measured flow rates from 0.1 to 5.0 liters/min.[16] The square wave electromagnetic flowmeter has a range of 5.0 ml/min to 19.99 liters/min, and has a frequency response that is flat to 90 hertz ± 0.5 decibels. The flowmeter output is linearly related to blood velocity or blood flow (±1 percent), and a previous evaluation[15] has shown the catheter-tip velocity probe to have a linear response to blood flow when measured against a cuff electromagnetic flow probe. The frequency response of the flow probe varies with the output filter in the flowmeter, and with 10 hertz filtering there was a 3.8 percent decrease in the amplitude of the peak phasic velocity between 1 and 10 hertz. There was a linear phase lag between 1 and 10 hertz, equal to a time lag of 20.85 ms.

Pressure and velocity tracings were recorded on a photographic recorder (Electronics for Medicine) at paper speeds of 50 and 100 mm/s. Phasic and mean blood flow velocity values were measured in the ascending aorta in 10 patients and in the distal conduit in 6. A withdrawal recording of phasic flow velocity was made from the upper thoracic aorta to the lumbar aorta below the conduit in 13 patients. The volume of blood flow (cc/min) was calculated from the mean flow velocity (cm/s) multiplied by the aortic or conduit cross-sectional area (cm^2) determined from the angiographic internal diameter. In six patients blood velocity was measured with the velocity probe well within the distal conduit (Fig. 1, Patient 1) and the conduit flow was expressed as a percent of the angiographically determined left ventricular output. To determine the conduit flow in the other seven patients, blood flow velocity was recorded in the descending aorta 2 cm above and 2 cm below the distal conduit anastomosis. In four of these patients the flow was entirely retrograde (negative deflection) above the conduit (Fig. 1, Patient 11). The phasic velocity tracings from above and below the conduit were measured with planimetry to obtain the stroke volume in each area. These values then were summed to obtain the conduit stroke volume through the conduit.

Three patients had a biphasic deflection recorded in the aorta above the conduit (Fig. 1, Patient 10). The area under both the negative (retrograde flow) and positive deflections (prograde flow) above the conduit were measured with planimetry, and the stroke volume in each direction was determined. If the net stroke volume was in a retrograde direction above the conduit, it was added to the calculated stroke volume in the aorta below the conduit; if the net flow above the conduit was prograde from the ascending aorta, this value was subtracted from the calculated stroke volume below the conduit to obtain the stroke volume that passed through the conduit.

Zero flow baseline was established with the catheter in a bowl of saline solution and also in the arterial sheath where electric and hydraulic zero flow levels were identical. Zero flow was determined while the catheter was in the aorta by switching off the magnet.

Systolic time intervals were measured using the velocity tracings from the ascending aorta and within the conduit in five patients. The preejection period was measured from the beginning of the Q wave to the onset of ejection in the velocity tracing. The ejection period was measured from the onset of ejection to the point when the velocity tracing crossed the zero flow baseline. The time required to achieve peak velocity (seconds) and peak velocity (cm/s) was measured.

Results

Left ventricular to aortic pressure gradient: In each patient there was a postoperative reduction in the pressure gradient between the body of the left ventricle and the upper thoracic aorta (Table II). The average pressure gradient was 100.6 mm Hg (range 54 to 140) preoperatively and 22.1 mm Hg (range 0 to 60) postoperatively (Fig. 2). Three patients (Cases 5, 6 and 13) had a residual gradient of greater than 30 mm Hg (Table III); each of them had higher than average cardiac output that may have contributed to the higher pressure gradient in these patients.

Cath = postoperative cardiac catheterization; CI = cardiac index (liters/min per m²); EDP = end-diastolic pressure (mm Hg); EDV %N = end-diastolic volume (percent normal); EF = ejection fraction (%); Hb = hemoglobin (g/100 ml); LV-Ao gradient = left ventricle to aorta pressure gradient (mm Hg); SD = standard deviation; SER = systolic ejection rate (vol/s); SI = stroke index (ml/m²); Vcf = velocity of circumferential fiber shortening (circumferences/s).

At previous operations, two patients had aortic valve replacement with a no. 17 Bjork valve for severe aortic valve stenosis with a small anulus. Postoperatively, both patients had severe intravascular hemolysis. In one patient the outflow gradient fell from 125 to 54 mm Hg after valve replacement in association with a chronic hemoglobin level of 7 to 8 g/100 ml and elevated plasma hemoglobin of 124 g/100 ml. After implantation of the conduit, the hemolysis ceased and the residual gradient was only 5 mm Hg, 33 percent of the left ventricular output traversing the conduit.[17]

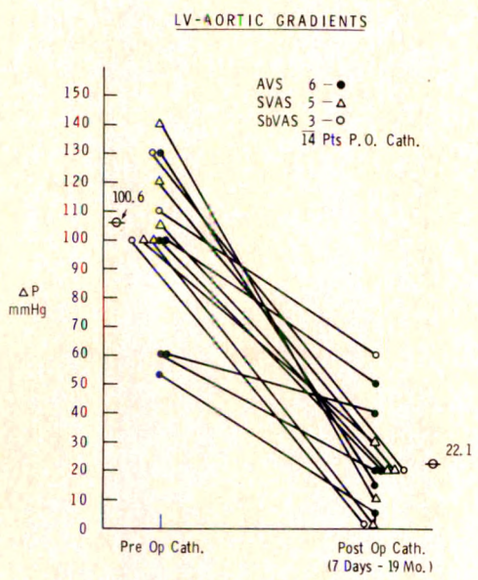

FIGURE 2. Left ventricle (LV) to aorta pressure gradients in 14 patients undergoing postoperative (P.O.) catheterization. AVS = aortic valve stenosis; ΔP = pressure gradient from left ventricle to aorta; SbVAS = subvalve aortic stenosis; SVAS = supravalve aortic stenosis. Mean preoperative (Pre op) and postoperative (Post op) pressures are signified by the **barred circles.**

Patient 2 was a 72 year old man with a heavily calcified ascending aorta and aortic valve and recent onset of angina due to atherosclerotic coronary artery disease. There was a 60 mm resting pressure gradient across the aortic valve preoperatively. Because it was not possible to insert saphenous vein bypass grafts into the calcified ascending aorta, an apical-aortic conduit was inserted and two saphenous veins were anastomosed to the conduit below the diaphragm and passed through the diaphragm for connection to the left anterior descending and left marginal coronary arteries.[18]

Left ventricular function (Table II): *Left ventricular end-diastolic pressure* was greater than 12 mm Hg in all but two of the patients who underwent catheterization within 13 days of operation; the patient with an end-diastolic pressure of 40 mm Hg had a pericardial effusion at the time of catheterization 7 days after operation. Of the four patients (Cases 3, 9, 11 and 14) who

EF (%)	68	72	NS
Mean Vcf (circumferences/s)	1.39	1.83	NS
Mean SER (vol/s)	2.14	2.73	NS

NS = not significant; p = probability; Postop = postoperative; preop = preoperative; other abbreviations as in Table II.

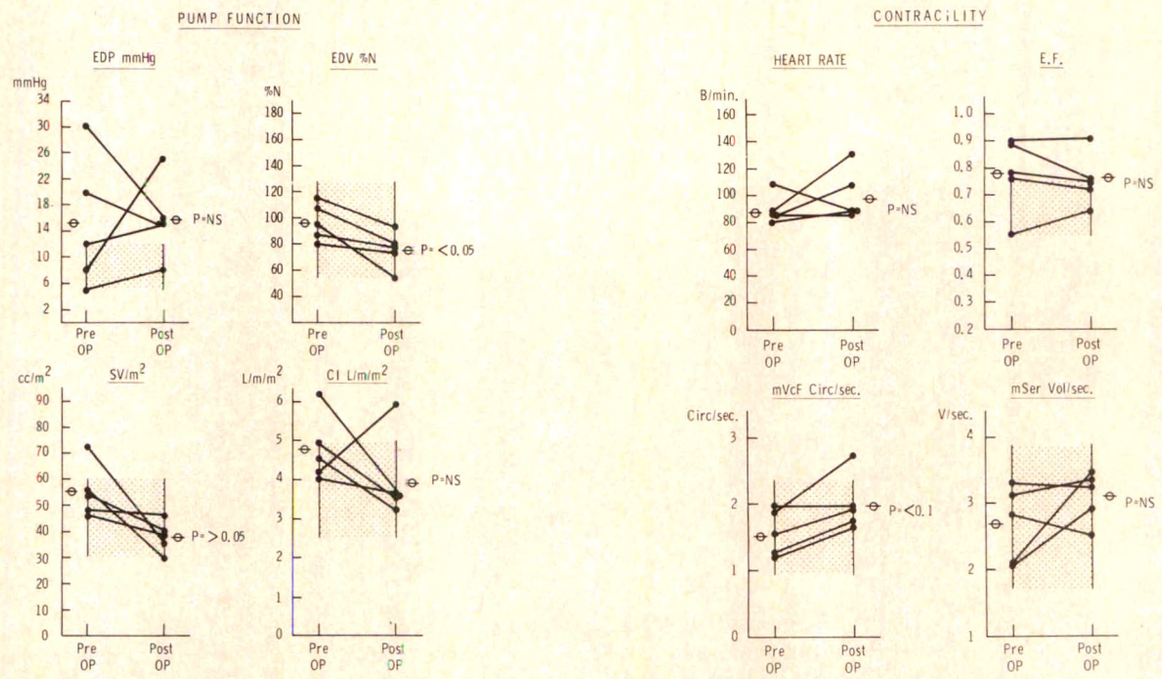

FIGURE 3. Comparison of preoperative and postoperative hemodynamics in five patients. **Stippled areas** = range of normal values. **Left,** pump function variables. CI = cardiac index (liters/min per m^2); EDP = end-diastolic pressure (mm Hg); EDV %N = end-diastolic volume (% normal); NS = not significant; P = probability; Post OP = postoperative; Pre OP = preoperative; SV/m^2 = stroke volume (cc/m^2).

underwent catheterization 8, 10, 3 and 12 months, respectively, after operation, three had a normal and one an elevated left ventricular and end-diastolic pressure. This last patient had Williams' syndrome[19] with supravalvular aortic stenosis, residual systemic hypertension and severe pulmonary branch stenosis.

Cardiac output and stroke index were normal or elevated in all patients except the patient (Case 2) who had coronary bypass surgery.

Ejection fraction was greater than 64 percent in all but two patients. There was a slight correlation between ejection fraction and age ($r = -0.55$). The ejection phase indexes of contractility, mean velocity of circumferential fiber shortening and mean systolic ejection rate, were normal in all but two patients (Table II).

Pre- and postoperative left ventricular performance was compared in 5 patients (Cases 3, 7, 8, 9 and 12) who had adequate pre- and postoperative catheterization and angiographic data (Fig. 3). Left ventricular function tended to be preserved or improved after the composite conduit implantation.

Conduit flow: The flow through the conduit averaged 36 percent (range 16 to 50) of the left ventricular output. In three patients less than 30 percent of left ventricular output passed through the conduit (Fig. 4).

Preoperative obliteration of the left ventricular cavity in seven patients ranged from 30 to 70 percent of the end-diastolic length (Fig. 5). Two of these patients were considered to have hypertrophic cardiomyopathy as well as fibromuscular subvalvular aortic stenosis.[20] Postoperative cavity obliteration was reduced in extent

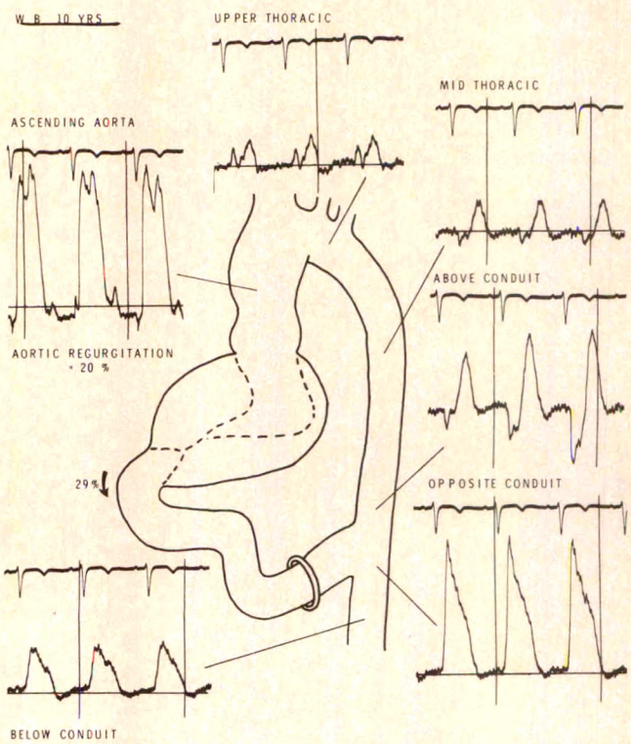

FIGURE 4. Patient 1. Velocity tracings from various positions in the aorta. There is mild aortic regurgitation amounting to 20 percent of forward stroke volume (as measured by planimetry). Above the conduit, the velocity tracing is biphasic showing an initial negative deflection (retrograde flow) followed by a larger positive deflection (prograde flow). The flow through the conduit by direct velocity measurements was 29% of the left ventricular output.

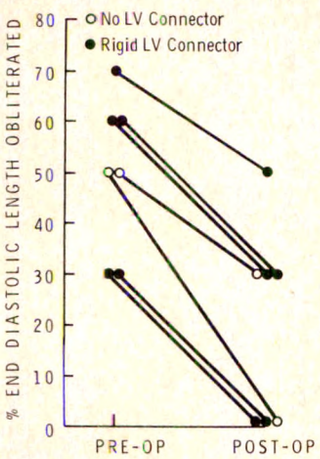

FIGURE 5. Preoperative (PRE-OP) and postoperative (POST-OP) left ventricular (LV) cavity obliteration expressed as a percent of the diastolic length.

in four patients and disappeared in three (Fig. 5). In four patients a rigid left ventricular connector was not inserted, and the conduit was sewn directly to the apical ventriculotomy. One of these patients had no cavity obliteration before or after operation; at postoperative catheterization the three other patients had reduction of the cavity obliteration from 50 percent preoperatively to 30 percent in two and to 0 percent in one. There was no compression of the unstented Dacron conduit at the apical anastomosis, and the cavity obliteration occurred at the left ventricular apex proximal to the anastomosis.

The four patients with persistent cavity obliteration postoperatively had an average conduit flow of 27.5 percent of left ventricular output (range 16 to 41 percent) and an average left ventricle to aorta gradient of 28.8 mm Hg (range 15 to 60). The patients who had no cavity obliteration after operation had an average conduit flow of 39 percent ($p < 0.1$) and an average left ventricular gradient of 19.5 mm Hg ($p < 0.5$). However, there was no statistical correlation between the extent of postoperative cavity obliteration and the volume of flow through the conduit ($r = -0.37$) or the residual gradient ($r = -0.18$).

Left ventricular angiography was unreliable in estimating the fraction of the left ventricular output passing through the conduit. When the angiographic catheter tip was near the apex, most of the contrast material appeared in the conduit. (Fig. 6). When the catheter tip was in the subaortic or inflow region more dye exited through the ascending aorta. In one patient, transseptal left ventriculography, with the catheter tip near the apex, showed an estimated conduit flow of about 70 percent, whereas a mid left atrial injection showed relatively even distribution of the contrast material between the ascending aorta and descending aorta. Blood flow calculated with use of the catheter-tip velocity probe was 41 percent through the conduit in this patient.

Five patients had blood flow velocity recordings in both the ascending aorta and in the conduit distal to the valve. Systolic time intervals were measured at comparable heart rates (Table IV). There were no significant differences between the preejection periods, times to peak velocity and the ejection times in the ascending aorta and conduit.

Aortic velocity patterns: In 10 patients, blood flow velocity tracings were obtained in the ascending aorta and in 13 patients in the upper and mid thoracic aorta

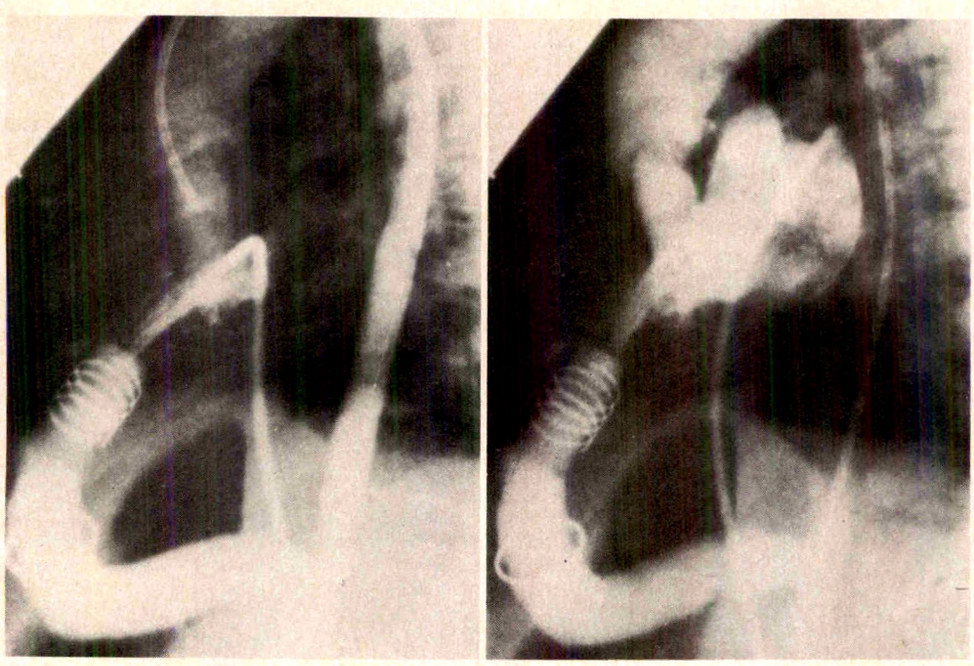

FIGURE 6. Patient 3. Lateral view of left ventricular cineangiogram (**left**) and left atrial cineangiogram (**right**) during ventricular systole. In **A**, the catheter tip is near the apex of the left ventricle and most of the contrast medium exits by way of the conduit. In **B**, there is even opacification of the ascending aorta and conduit. The calculated flow through the conduit from velocity tracings was 41 percent of the left ventricular output.

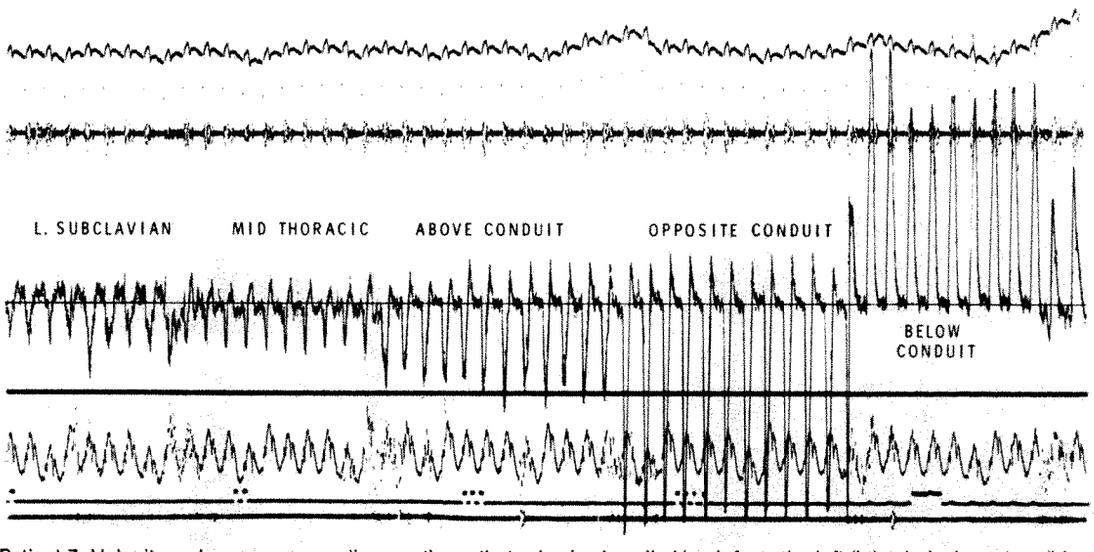

FIGURE 7. Patient 7. Velocity and pressure recordings as the catheter is slowly pulled back from the left (L.) subclavian artery (blood flow away from the catheter tip) to the descending aorta below the conduit anastomosis (blood flow toward the catheter tip). There is mostly retrograde blood flow from the conduit toward the aortic arch.

and above and below the conduit anastomosis (Fig. 7). Seven patients had a predominantly negative velocity wave (retrograde flow) above the conduit and in the mid thoracic aorta, whereas six patients had a positive velocity wave in the mid thoracic aorta and a negative or biphasic wave above the conduit (Fig. 8). Patients with prograde flow in the mid thoracic aorta had slightly less blood flow through the conduit (average 30 versus 41 percent of left ventricular output) and a slightly higher residual pressure gradient (average 27.3 versus 17.9 mm Hg) than those of patients with retrograde flow in the mid thoracic aorta. Residual cavity obliteration was seen in three of the former group and in only one of the latter group (Fig. 8).

Mid thoracic angiography: In nine patients an angiogram was performed in the mid to lower thoracic aorta, four vertebral bodies above the level of the conduit insertion. Retrograde flow of contrast material was observed in all patients, to the ascending aorta in three, the aortic arch in one, to the level of the fifth thoracic vertebra in two patients and to the sixth or seventh thoracic vertebra in three.

Clinical follow-up: *There were three late deaths among the 25 survivors.* One was in a 12 year old boy* who had bacterial endocarditis that developed on the porcine valve; he died 3 months postoperatively with diffuse sepsis and empyema. The second was in a 10 year old girl* who had had three previous subaortic resections and two repairs of aortic coarctation. She had two transient cerebral ischemic episodes 6 months postoperatively and died of a massive cerebrovascular hemorrhage. At autopsy, she was found to have an arterial malformation of the right middle cerebral artery with extensive thrombosis. No emboli were seen in the brain, and there were no thrombi on the porcine valve

* Catheterization was not performed in these two patients, and they are not included in the preceding patient data or tables.

Ao = ascending aorta; Con = distal conduit; HR = heart rate (beats/min); LVET = left ventricular ejection time; NS = not significantly different; p = probability; PEP = preejection period; Pred = predicted value[24]; SD = standard deviation.

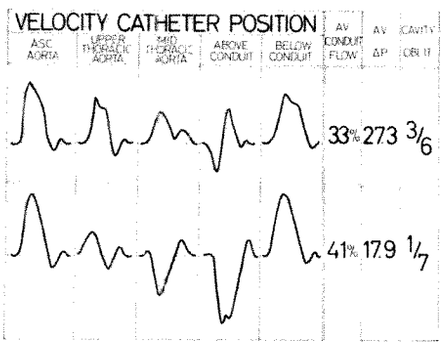

FIGURE 8. Representative tracings of velocity wave forms in two groups of patients. **Upper tracings,** from six patients who had a positive velocity deflection in the mid thoracic aorta. **Lower tracings,** from seven patients who had a negative velocity deflection in the mid thoracic aorta. AV conduit flow = average percent of left ventricular output flowing through the conduit; AVΔP = average pressure gradient (mm Hg) from the left ventricle to the aorta; cavity oblit. = number of patients with angiographic cavity obliteration postoperatively.

or in the left ventricle; the arterial malformation may have been associated with the persistent coarctation. In the third patient (Case 12) death occurred 3.5 years after operation. At autopsy, this patient had a retroperitoneal hematoma attributed to a consumptive coagulopathy that was not thought to be related to the conduit. There was also partial disruption of the left ventricular apex fabric graft anastomosis with pseudoaneurysm formation.

No patient was given anticoagulant agents postoperatively. One patient (Case 13) had thrombotic occlusion of the aortic bifurcation 3 months after operation. The thrombus was removed surgically and warfarin therapy was instituted. Two months later, while still receiving warfarin, she had a pulmonary embolus during operation for tubal ligation; she eventually made a full recovery.

Six children have been followed up personally by one of us (MRN) for 14 to 48 months postoperatively. All are symptomatically improved with no complications from the conduit. One patient has persistent premature ventricular complexes that were present before operation; one patient with Williams' syndrome has systemic hypertension that is well controlled with diuretic drugs and methyldopa. Two children have had normal treadmill tests. The well-being of the other patients was ascertained from their cardiologists.

Discussion

Placing a valved conduit from the apex of the left ventricle to the supraceliac abdominal aorta is an effective method of reducing left ventricular outflow tract pressure gradients when traditional methods of surgical repair are ineffective. Only three patients had a residual left ventricle-to-aorta gradient of greater than 30 mm Hg and each had a significantly higher cardiac index and left ventricular end-diastolic pressure than the other patients as a group. It is possible that the high cardiac output at the time of cardiac catheterization contributed to the higher residual gradient. None of the patients underwent exercise testing during catheterization, but the pressure gradients remained reasonably constant 2 minutes after angiography. Reports from others[1-3,6,7,18] using various forms of conduit from the left ventricular apex to the ascending or thoracic descending aorta have confirmed the effectiveness of this operation from 3 to 6 months postoperatively with good long-term results and few untoward sequelae.

Conduit flow: Blood flow from the conduit was calculated using measurements of blood flow velocity obtained with a catheter-tip velocity probe. The velocity catheters were calibrated in vitro so that the recorded velocity was the same as the calculated velocity at a known blood flow. The two exits from the left ventricle made it impossible to calibrate the velocity recordings with indocyanine green cardiac output measurements in the patients at the time of catheterization. However, in vivo calibrations correlated well with calculated velocities obtained in other patients in whom simultaneous velocity and cardiac output measurements were made (Nihill MR, unpublished data).

Use of a velocity catheter to measure regional blood flow was found to be more reliable than left ventricular angiography in estimating the amount of blood flow through the conduit. During angiography the amount of contrast material leaving the left ventricle by way of the conduit or the aorta was dependent on the position of the catheter tip. Left atrial or left ventricular inflow angiography produced a better visual estimate of blood flow distribution than that obtained with the angiographic catheter tip placed near the orifice of the conduit.

The hemodynamics and velocity wave forms in the apical conduit were identical to those in the ascending aorta with the same systolic time intervals and ejection velocity patterns. The measured systolic time intervals were very similar to predicted values.[24] The higher peak velocity in the ascending aorta was due to the jet effect from persistent aortic stenosis.

The descending thoracic aortograms confirmed the retrograde flow of blood from the conduit toward the head. The degree of retrograde flow correlated well with the negative deflection recorded by the velocity catheter positioned above the distal conduit anastomosis. It has been shown experimentally that the conduit is able to sustain the entire left ventricular output when the ascending aorta is clamped.[4]

Cavity obliteration: Left ventricular cavity obliteration occurs in patients with various forms of left ventricular outflow tract obstruction,[14] as well as in those with primary hypertrophic cardiomyopathy.[21,22] Two of the four patients (Cases 12 and 13) with residual cavity obliteration previously had undergone resection of a fibromuscular ridge below the aortic valve. The persistent obstruction after the conduit operation was related to mid cavity obliteration rather than to obstruction at the subaortic area or at the conduit orifice. Both of these patients had lower than average flow through the conduit (24 and 16 percent, respectively) and had residual gradients of 20 and 60 mm Hg, re-

spectively. It is possible that these patients also had hypertrophic cardiomyopathy associated with fibromuscular subaortic stenosis.[23]

Although cavity obliteration was reduced in all patients who had it before operation, the use of a left ventricular apex outlet prosthesis did not abolish cavity obliteration. Cavity obliteration persisted postoperatively in only two of the four patients in whom a rigid left ventricular connector was not used. In the four patients without a stented conduit, angiography revealed no evidence of proximal conduit compression during systole, which has been assumed by others.[3] Long-term reevaluation with angiography and echocardiography will determine whether left ventricular hypertrophy and cavity obliteration will continue to regress after the relief of left ventricular hypertension.

Left ventricular function: Left ventricular function was preserved or improved in most patients after operation. Cardiac catheterization several months after operation would give a more accurate assessment of left ventricular function when postoperative changes have disappeared. Ten of the postoperative catheterizations were performed within 13 days of operation (median 11 days), and it is possible that left ventricular dysfunction observed in some of our patients was a consequence of the ischemic arrest during cardiopulmonary bypass, together with postoperative anemia. However, when these patients as a group were compared with the four patients who underwent catheterization 3 to 18 months postoperatively, the only differences observed were in the hemoglobin level (10.84 ± 1.35 versus 14.2 ± 1.62 g/100 ml, $p < 0.005$), the residual pressure gradient (26.0 ± 10 versus 12.5 ± 15 mm Hg, $p > 0.2$) and the left ventricular end-diastolic pressure (17.7 ± 9.7 versus 11.25 ± 4 mm Hg, $p > 0.2$). The other measured indexes of left ventricular function (Table II) were not significantly different in the early and late postoperative catheterization groups. Left ventricular function as assessed from the hemodynamic variables and angiography was normal in most patients 7 days or later after operation, as would be expected if there was adequate relief of the left ventricular outflow obstruction and the effects of cardiopulmonary bypass had disappeared.[24,25]

There was no apparent deleterious effect from fixing the apex of the left ventricle to the diaphragm, as has been shown in long-term studies of dogs by Sarnoff[4] and Ferguson[26] and their co-workers. The fractionation of left ventricular output by ejection of blood in opposite directions does not appear to affect adversely the distribution of blood flow to the body once the blood enters the aorta. If the cross-sectional area of the normal left ventricular outflow tract is less than that of the valved conduit, more blood will flow through the conduit to distribute the cardiac output in a normal fashion, even to vessels of the aortic arch.[27] No patient had evidence of coronary or cerebral steal due to excessive flow through the conduit to the lower half of the body.

Anticoagulant agents: No anticoagulant agents were used in these patients. However, we currently recommend that patients receiving composite conduit implantations be given aspirin and dipyridamole postoperatively.

Follow-up: Six children (aged 5 to 18 years at the time of operation) have been followed up personally for 14 to 48 months postoperatively. All have shown postoperative improvement in exercise tolerance and all are growing and developing normally. In two, a treadmill exercise test revealed no evidence of left ventricular strain or ischemia on the electrocardiogram.

Although the follow-up period for our patients is only 4 years, their continued well-being and clinical stability, plus the satisfactory hemodynamic status of the four patients who underwent catheterization 3 months or later after operation, suggest that this conduit is well tolerated and effective over a long period. However, the long-term prognosis for this type of operation is not yet known. It will be desirable to repeat the catheterization in children after puberty to determine if an increase in the left ventricle to aorta gradient occurs.

Further studies—cardiac catheterization, M mode and cross-sectional echocardiography and radionuclide studies—will be used to assess left ventricular function, wall thickness and the response of the left ventricle to exercise. Radionuclide studies may help to determine more accurately the amount of blood flow through the conduit, and serial measurements could help to determine the optimal time for replacing the conduit valve in growing children.

Conclusion: Analysis of pressure, angiographic and arterial velocity patterns has shown that (1) this operation is effective in relieving severe left ventricular-aortic pressure gradients that are not relieved by other surgical techniques; (2) left ventricular function is preserved or improved in the early postoperative period; (3) blood flow is distributed normally to the body; and (4) the amount of blood flow through the conduit is dependent on the degree of left ventricular outflow tract obstruction. Follow-up of some of these patients for up to 48 months postoperatively has shown that this operation is tolerated well and permits normal exercise and growth and development in children.

an important
advancement . . .
to fill a gap
in oral
procainamide
therapy

Parke-Davis introduces

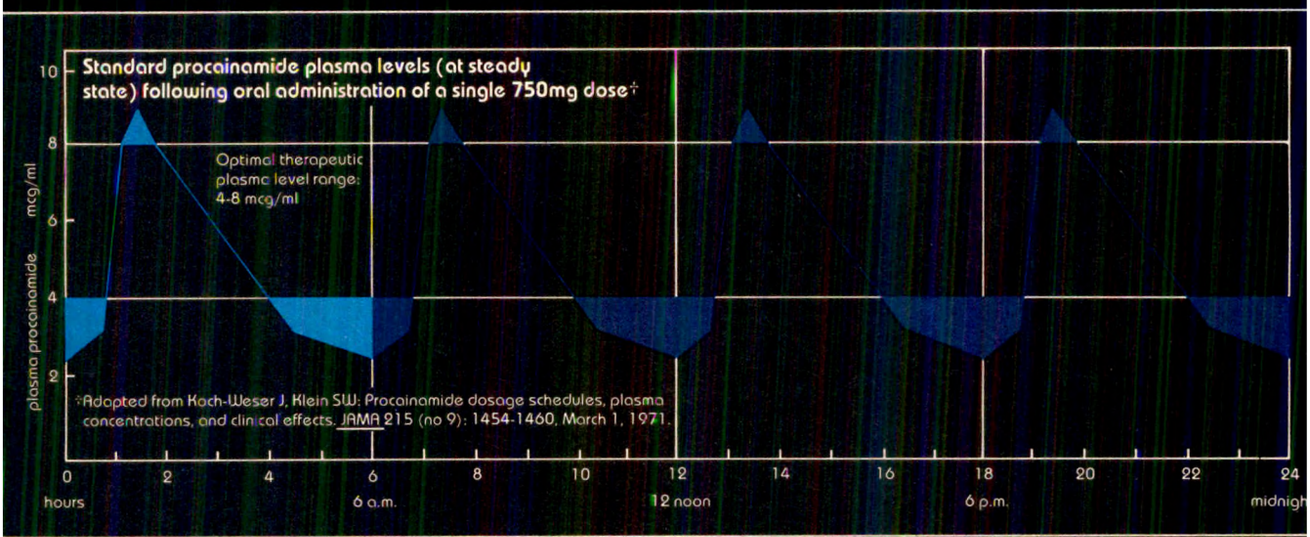
SUSTAINED RELEASE

new Procan™ SR

(PROCAINAMIDE HYDROCHLORIDE TABLETS

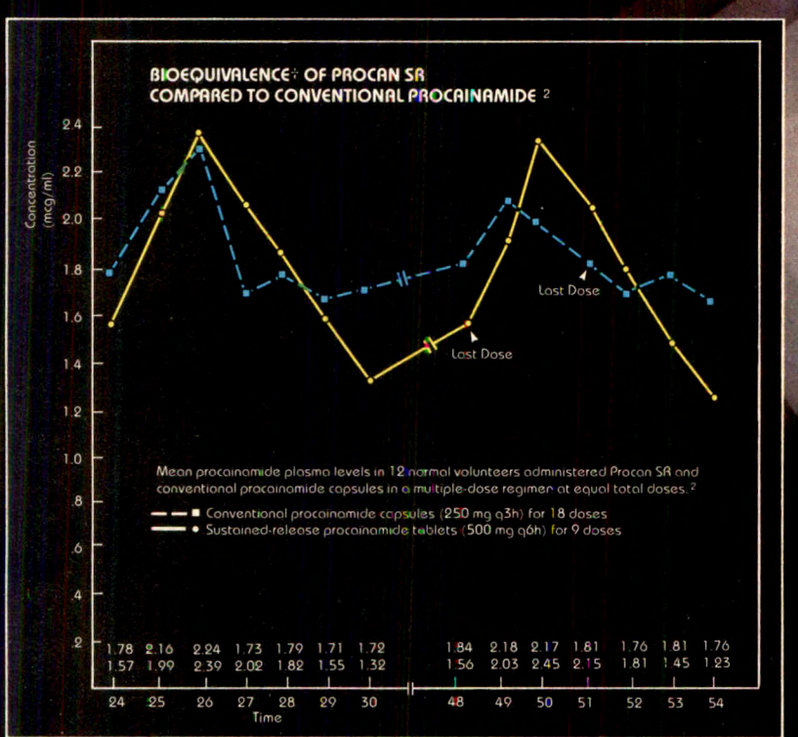
a therapeutic gap exists when conventional oral procainamide therapy is administered at greater than 3 hour intervals

- Adequate blood levels maintained only 2/3 of the time during a 6 hour dosing interval
- Patient control may be threatened



"To avoid unacceptable fluctuations in the plasma levels of procainamide, the oral preparation available at present has to be given at 3 h intervals . . . .[1]"

Bioequivalence of PROCAN SR to conventional procainamide capsules demonstrated in multi-dose study[2]

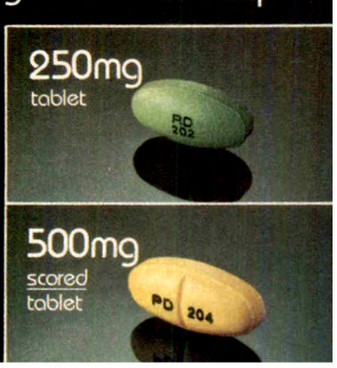


for selected cardiac dysrhythmias

- Cuts the dosing frequency of conventional oral procainamide therapy **in half**
- Promotes better patient **compliance**
- Helps eliminate the therapeutic gap and maintains blood levels **all day** and **all night**

- Formulated using a special wax matrix — permit slow dissolution

2 strengths for greater flexibility



Procan™ SR

(PROCAINAMIDE HYDROCHLORIDE TABLETS)

SUSTAINED RELEASE

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

DESCRIPTION

Procainamide hydrochloride is the amide analogue of procaine hydrochloride. Each tablet of Procan SR contains procainamide hydrochloride in a tablet matrix specially designed for the prolonged release of the drug in the gastrointestinal tract. Procan SR is available for oral administration as green, film-coated tablets containing 250 mg procainamide hydrochloride and as yellow, film-coated tablets containing 500 mg procainamide hydrochloride.

ACTION

Procainamide depresses the excitability of cardiac muscle to electrical stimulation, and slows conduction in the atrium, the bundle of His, and the ventricle. The refractory period of the atrium is considerably more prolonged than that of the ventricle. Contractility of the heart is usually not affected nor is cardiac output decreased to any extent unless myocardial damage exists. In the absence of any arrhythmia, the heart rate may occasionally be accelerated by conventional doses, suggesting that the drug possesses anticholinergic properties. Larger doses can induce atrioventricular block and ventricular extrasystoles which may proceed to ventricular fibrillation. These effects on the myocardium are reflected in the electrocardiogram; a widening of the QRS complex occurs most consistently; less regularly, the P-R and Q-T intervals are prolonged, and the QRS and T waves show some decrease in voltage.

The sustained-release characteristic of Procan SR tablets has been demonstrated in studies in human subjects. A multiple-dose study has shown equivalent steady-state plasma levels of Procan SR tablets given every six hours when compared with an equal total daily dose of Pronestyl® (procainamide hydrochloride capsules, E.R. Squibb and Sons) given every three hours.

Procainamide is less readily hydrolyzed than procaine, and plasma levels decline slowly — about 10 to 20% per hour for standard dosage forms of procainamide. The drug is excreted primarily in the urine, about 10% as free and conjugated p-aminobenzoic acid, and about 60% in the unchanged form. The fate of the remainder is unknown.

INDICATIONS

Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS

It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS

During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient re-evaluated because asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney diseases, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs'-positive hemolytic anemia have been reported which may be related to this syndrome. Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

ADVERSE REACTIONS

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS). Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

DOSAGE AND ADMINISTRATION

Procan SR tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every three hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia — Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dosage of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia — Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dosage of 0.5 g to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED

N 0071-0202 Procan SR 250 mg. Each sustained-release tablet contains 250 mg procainamide hydrochloride. Available in bottles of 100 tablets.

N 0071-0204 Procan SR 500 mg. Each sustained-release, scored tablet contains 500 mg procainamide hydrochloride. Available in bottles of 100 tablets.

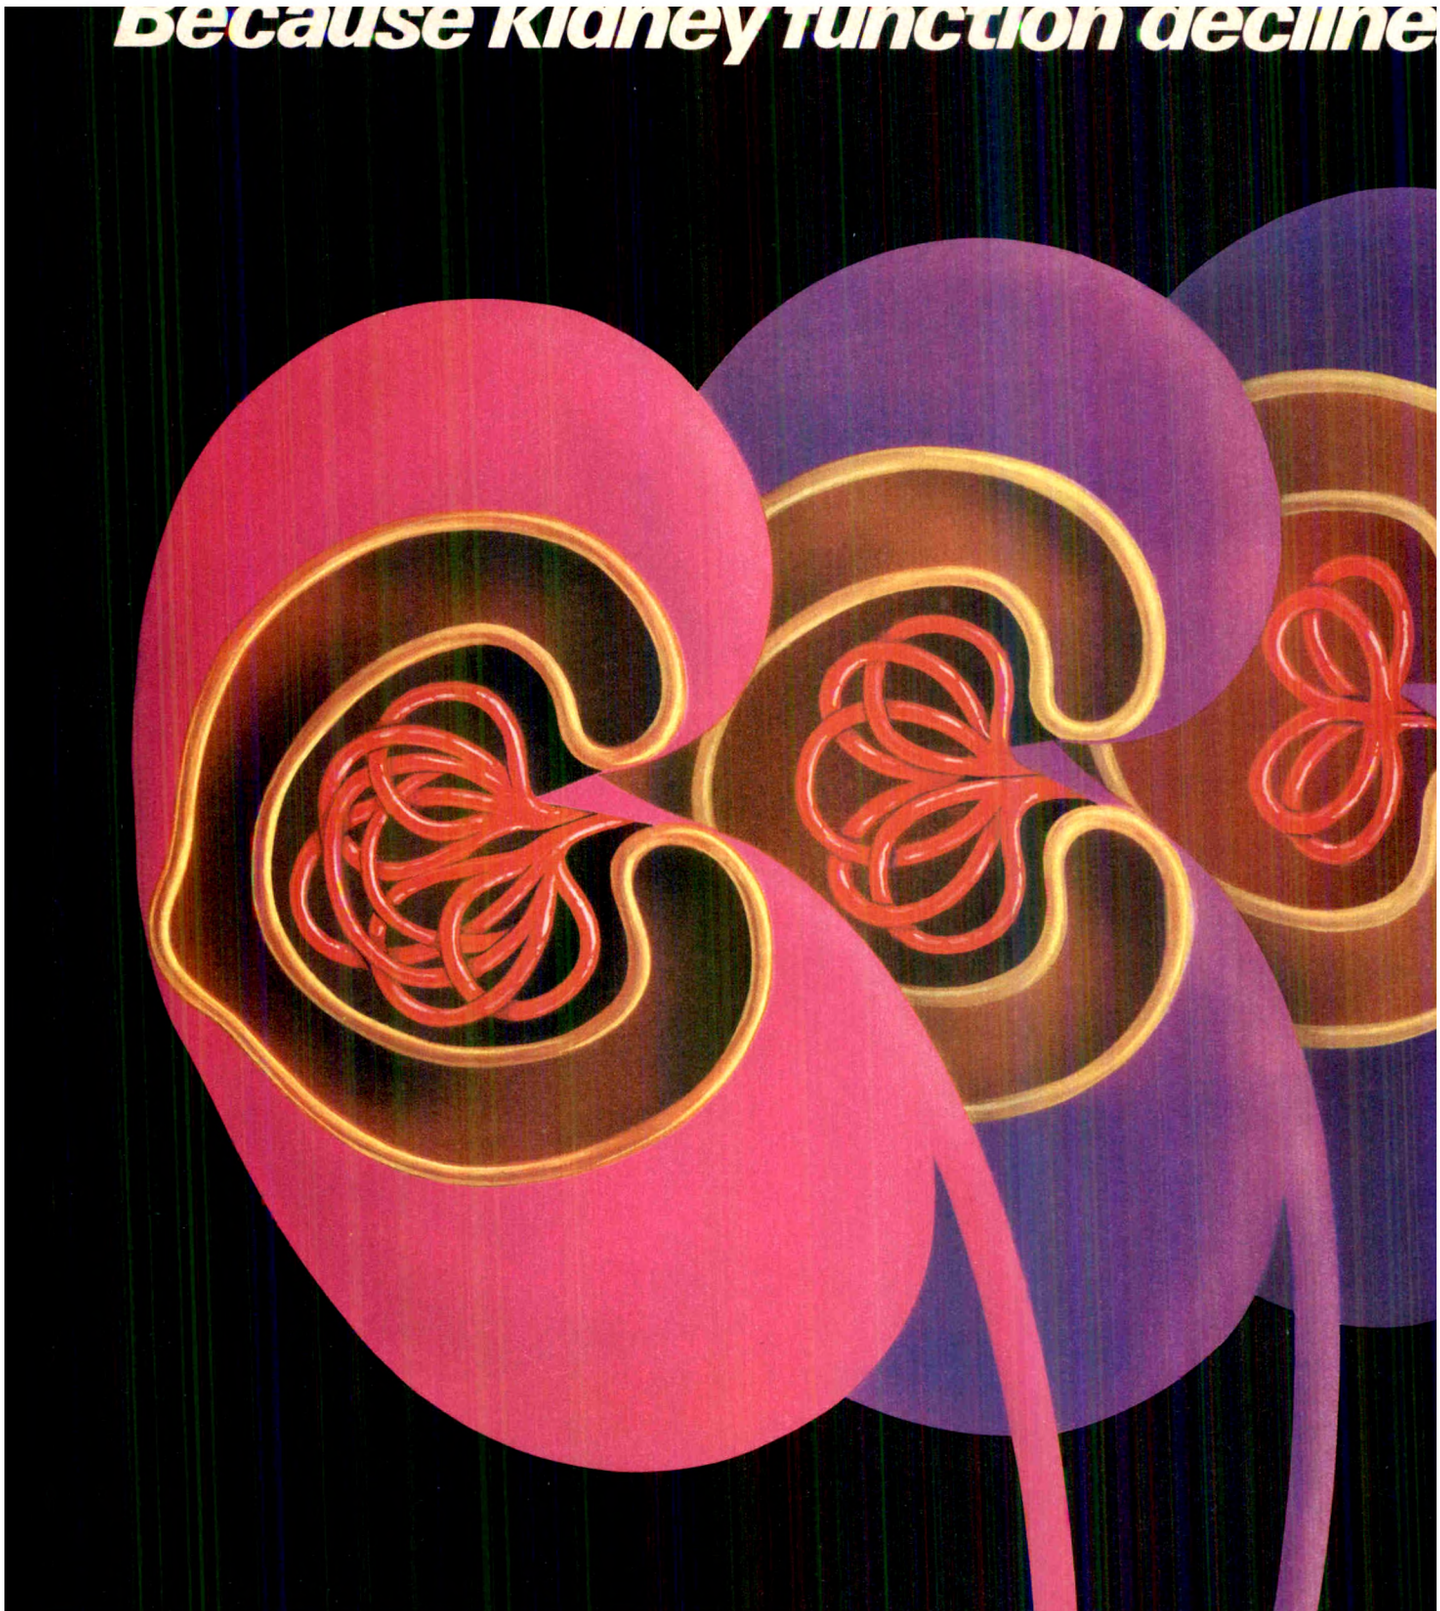
Because kidney function decline



DIULO™ (metolazone) 2½-mg., 5-mg. and 10-mg. tablets *Before prescribing, see complete prescribing information. The following is a brief summary:* ***Indications:*** *Diulo (metolazone) is an antihypertensive diuretic indicated for the management of mild to moderate essential hypertension as sole therapeutic agent and in the more severe forms of hypertension in conjunction with other antihypertensive agents. Also, edema associated with heart failure and renal disease.* ***Contraindications:*** *Anuria, hepatic coma or precoma; allergy or sensitivity to metolazone.* ***Warnings:*** *In theory, cross-allergy may occur in patients allergic to sulfonamide-derived drugs, thiazides or quinethazone. Hypokalemia may occur, and is a particular*

Azotemia and hyperuricemia may be noted or precipitated. Considerable potentiation may occur when given concurrently with furosemide. When added to other antihypertensives, the dosage of the other agents should be reduced. Use with potassium-sparing diuretics may cause potassium retention and hyperkalemia. Administration to pregnant women or those of childbearing age requires that potential benefits be weighed against possible hazards to the fetus. Metolazone appears in the breast milk. Not recommended for pediatric use. ***Precautions:*** *Perform periodic examination of serum electrolytes, BUN, uric acid, and glucose. Observe patients for signs of fluid or electrolyte imbalance, hyponatremia, hypochloremic*

With age...

DIULO
(METOLAZONE)

In hypertension...the only 24-hour acting diuretic that is effective even when kidney function is depressed

Statistics released by the National Institute on Aging show that renal function decreases with age – a decline most predictable in middle and old age, at just the time when hypertension often manifests itself. Thus, at some clinically unpredictable point, the pharmacology of a particular diuretic may no longer match your patient's pathophysiology; thus, therapy may become less effective. Because precise evaluation of renal function is often impracticable in the outpatient setting, it makes sound clinical sense to use a diuretic that continues to be effective as kidney function declines.

Works even when kidney function is depressed

Diulo works to lower blood pressure when kidney function is normal and may even produce diuresis and blood pressure reduction in patients with glomerular filtration rates below 20 ml/min. Through a unique secondary mode of action, it exerts an effect that differs from that of the thiazides or chlorthalidone.

Provides a 24-hour duration of action

Diulo permits a dosage regimen of one tablet a day, which encourages patient compliance. Furthermore, peak activity occurs during waking hours, minimizing the potential for nighttime urination.

SEARLE *Searle Laboratories*
Division of Searle Pharmaceuticals Inc.
Box 5110
Chicago, Illinois 60680

when there is excessive vomiting or diarrhea, or when parenteral fluids are administered. Patients treated with diuretics or corticosteroids are susceptible to potassium depletion. Caution should be observed when administering to patients with gout or hyperuricemia or those with severely impaired renal function. Insulin requirements may be affected in diabetics, and hyperglycemia and glycosuria may occur in latent diabetes. Chloride deficit and hypochloremic alkalosis may occur. Orthostatic hypotension may occur. Dilutional hyponatremia may occur. ***Adverse Reactions:*** *Constipation, nausea, vomiting, anorexia, diarrhea, bloating, epigastric distress, intrahepatic cholestatic jaundice, hepatitis, syncope, dizziness, drowsiness, vertigo, headache, orthostatic hypotension, excessive volume depletion, hemoconcentration, venous thrombosis, palpitation, chest pain, leukopenia, urticaria, other skin rashes, dryness of mouth, hypokalemia, hyponatremia, hypochloremia, hypochloremic alkalosis, hyperuricemia, hyperglycemia, glycosuria, raised BUN or creatinine, fatigue, muscle cramps or spasm, weakness, restlessness, chills, and acute gouty attacks.* ***Usual Initial Once-Daily Dosages:*** *Mild to moderate essential hypertension—2½ to 5 mg.; edema of cardiac failure—5 to 10 mg.; edema of renal disease—5 to 20 mg. Dosage adjustment is usually necessary during the course of therapy.* ***How Supplied:*** *Tablets, 2½, 5 and 10 mg.; in bottles of 100.*

THE TRENDSETTER.

A DYNAMIC, NEW CARDIOVASCULAR SYSTEM FOR IMPROVED PATIENT MANAGEMENT FROM DEL MAR AVIONICS.

CAN REEL-TO-REEL, CARTRIDGE, OR CASSETTE RECORDINGS.
The Trendsetter handles *all*.

DETECT ARRHYTHMIAS WITH UNPARALLELED ACCURACY.
The system's Arrhythmia Analyzer is "operator-taught" to recognize each patient's unique normal and variant waveforms, and to compare all subsequent waveforms to the learned patterns. The Analyzer then categorizes and counts all such waveforms—making arrhythmia detection precise and specific for each patient.

REDUCE PROCESSING TIME WITH NEW X240 SCANNING SPEED.
Selectable scan speeds of X240, X120 or X60 provide the operator with a speed-control range to assist in generating comprehensive reports rapidly—all with complete accuracy.

EVALUATE AMBULATORY ECG, BLOOD PRESSURE, AND PACEMAKER RECORDINGS WITH A SINGLE INTEGRATED SYSTEM.
The Trendsetter learns, examines, tabulates, and formats reports of all recorded data.

SELECT REPORT FORMATS TAILORED TO YOUR DIAGNOSTIC NEEDS.
Select the information you require to better manage each patient:

- Trend records of heart rate
- ST segment level and blood pressure
- 2-channel ECG documentation
- Hourly tabulations of ECG activity, pacemaker activity, and blood pressure
- Graphic/histographic charts of recorded data
- Any combination you predetermine

STORE MULTIPLE PATIENT FINDINGS WITH INTEGRAL COMPUTER DATA STORAGE MODULE.
Recorded data for up to 30 patients can be stored and recalled for subsequent review and formatting.

If the stocking you're using doesn't have this symbol

it's not a T.E.D.® Stocking and it's not clinically proven.

Anti-embolism stockings are a prescription product designed to save lives. But only T.E.D. Anti-Embolism Stockings by Kendall have actually been clinically proven.

It's as simple as that.

T.E.D. Stockings have 25 years of clinical research behind them to demonstrate that they reduce the incidence of deep vein thrombosis[1,2,3] and reduce the incidence of pulmonary embolism.[4,5] No other manufacturer of anti-embolism stockings can say that. And T.E.D. Stockings are backed by sophisticated manufacturing techniques, and strict standards of quality control, as well as the most comprehensive program of inservice literature and training. No other manufacturer of anti-embolism stockings can say that.

Anti-embolism stockings can look alike. But if the stocking you're using doesn't have the symbol on the instep – it's not a T.E.D. Stocking and it's not clinically proven.

KENDALL
INNOVATORS IN PATIENT CARE

If you feel strongly that the anti-embolism stockings used in your hospital should be clinically proven, return the coupon and we will bring your feelings to your hospital's attention.

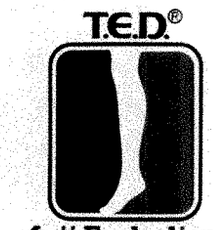
ANTI-EMBOLISM
STOCKING
NYLON
THIGH LENGTH
MEDIUM
REGULAR



Contraindications:

Stockings may not be recommended for patients with the following:

1. Any local leg condition in which stockings would interfere, such as:
   a. dermatitis,
   b. vein ligation (immediate post-operative),
   c. gangrene,
   d. recent skin graft.
2. Severe arteriosclerosis or other ischemic vascular disease.
3. Massive edema of legs or pulmonary edema from congestive heart failure.
4. Extreme deformity of leg.
5. For thigh length, patients with a circumference greater than 25 inches (63.5cm) at the gluteal furrow. For full leg (X-S, S, M, L), patients with a circumference of 25 inches (63.5cm) or greater at the gluteal furrow. For full leg (X-L), patients with a circumference of greater than 32 inches (81.3cm) at the gluteal furrow.

Precautions:

1. Proper sizing and application must be assured.
2. For full leg style T.E.D.® Stockings, avoid interference of side panels or waistband with incisions, drainage tubes, catheters or other exterior devices.

Warnings:

Caution: Federal (U.S.A.) Law restricts this device to sale by or on the order of a physician.

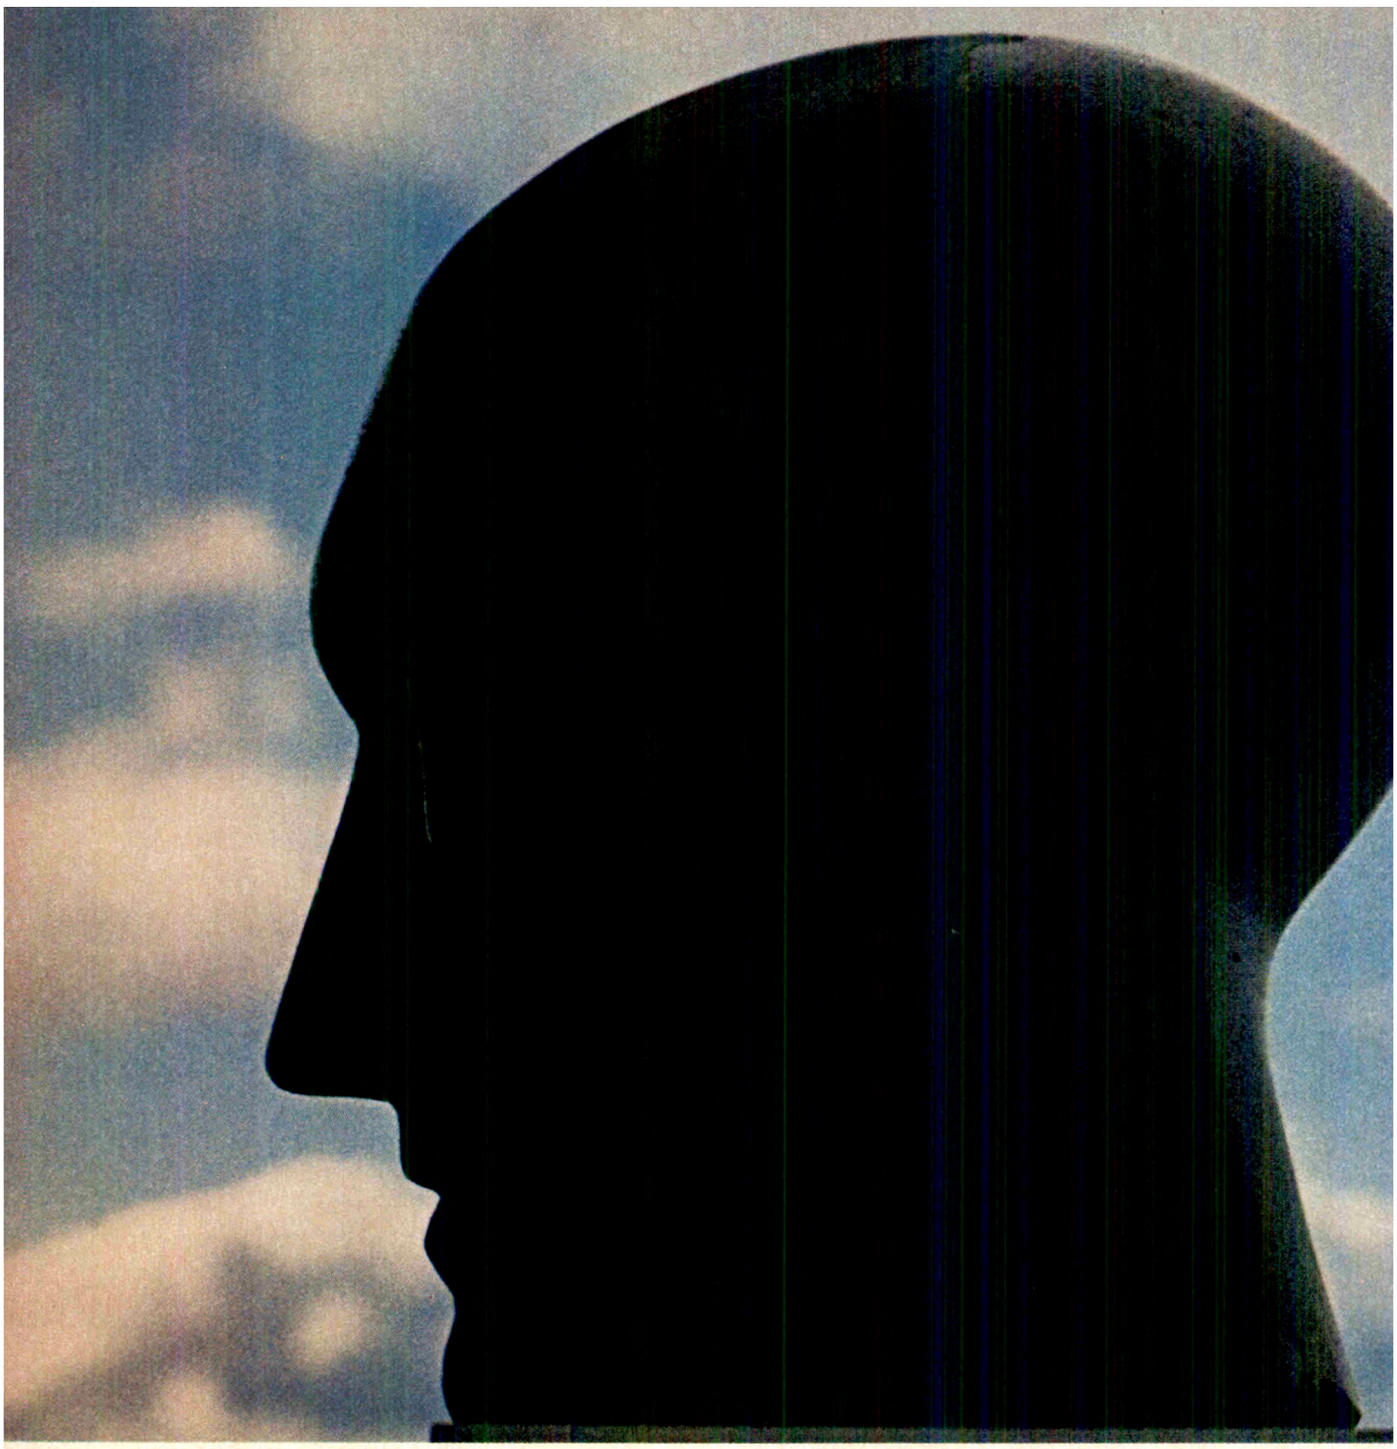
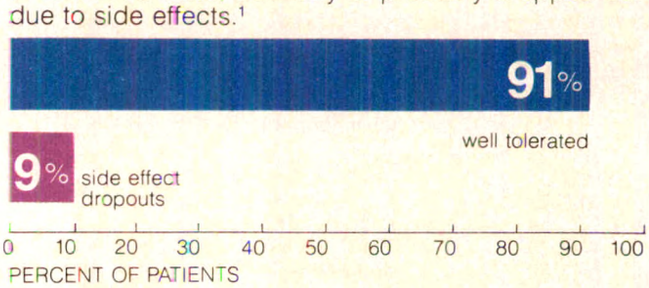
AMEREC



Combipres.® Today and Tomorrow

well tolerated—only 9% of 484 patients, in 16 clinical trials, definitely or probably dropped out due to side effects.[1]



Effective control in (mild to moderate) hypertension usually with just 2 or 3 tablets daily.

Low incidence of depression, and orthostatic hypotension.*

The most common side effects are dry mouth, drowsiness, and sedation, which generally tend to diminish with time. As with other antihypertensives containing diuretic agents, hypokalemia, hyperuricemia, and hyperglycemia may occur. Drowsiness and sedation may be alleviated by giving the larger portion of the divided dose at bedtime.[2,3]

Convenient morning and bedtime dosage scheduling.

Combipres®

Each tablet contains: Catapres* (clonidine HCl) 0.1 or 0.2 mg, and chlorthalidone, 15 mg

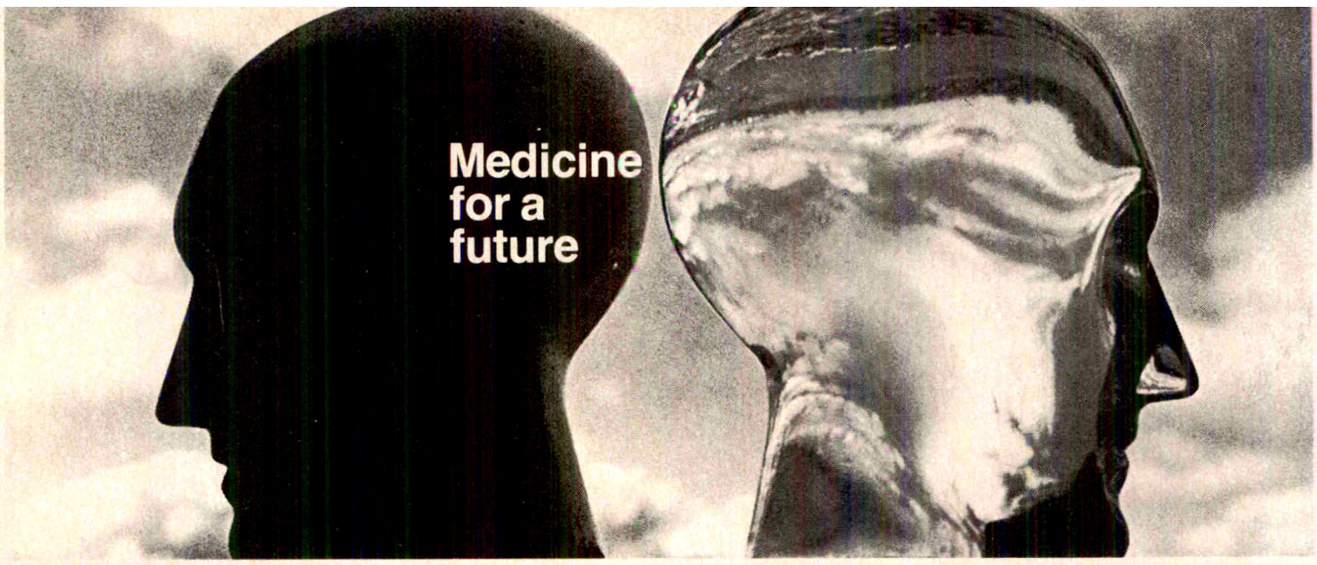
.1 and .2

HYPERTENSION

Combipres is not indicated for initial therapy. It is for patients responsive to its components given separately in equivalent dosages.

Please see brief summary of the prescribing information on the last page of this ad for warnings, precautions, and adverse reactions.

*Orthostatic hypotension has been reported with chlorthalidone and may be potentiated when chlorthalidone is combined with alcohol, barbiturates, or narcotics.



Combipres® .1 and .2

Each tablet contains: Catapres* (clonidine HCl) 0.1 or 0.2 mg, and chlorthalidone, 15 mg

Warning: This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

Indication: The drug is indicated in the treatment of hypertension (see box warning).

Contraindications: Patients with known hypersensitivity to chlorthalidone and patients with severe renal or hepatic diseases.

Warnings: Tolerance may develop in some instances necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxicity findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefit outweighs the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Combipres in children.

Precautions: When discontinuing Combipres, reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of Combipres therapy or by intravenous phentolamine.

Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect of the clonidine hydrochloride component.This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other antihypertensive agent, Combipres should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Combipres should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmological findings have been recorded with Catapres, in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Patients predisposed toward or affected by diabetes should be tested periodically while receiving Combipres, because of the hyperglycemic effect of chlorthalidone.

Because of the possibility of progression of renal failure, periodic determination of the BUN is indicated. If, in the physician's opinion, a rising BUN is significant, the drug should be stopped.

The chlorthalidone component of Combipres may lead to sodium and/or potassium depletion. Muscular weakness, muscle cramps, anorexia, nausea, vomiting, constipation, lethargy or mental confusion may occur. Severe dietary salt restriction is not recommended in patients receiving Combipres.

Periodic determinations of the serum potassium level will aid the physician in the detection of hypokalemia. Extra care should be given to detection of hypokalemia in patients receiving adrenal corticosteroids, ACTH or digitalis. Hypochloremic alkalosis often precedes other evidence of severe potassium deficiency. Frequently, therefore, more sensitive indicators than the potassium serum level are the serum bicarbonate and chloride concentrations. Also indicative of potassium depletion can be electrocardiographic alterations such as changes in conduction time, reduction in amplitude of the T wave; ST segment depression; prominent U wave. These abnormalities may appear with potassium depletion before the serum level of potassium decreases. To lessen the possibility of potassium deficiency, the diet, in addition to meat and vegetables, should include potassium-rich foods such as citrus fruits and bananas. If significant potassium depletion should occur during therapy, oral potassium supplements in the form of potassium chloride (3 to 4.5 gm day), fruit juice and bananas should be given.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy.

Clonidine hydrochloride: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one case of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure. Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash; impotence, urinary retention; increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Chlorthalidone: Symptoms such as nausea, gastric irritation, anorexia, constipation and cramping, weakness, dizziness, transient myopia and restlessness are occasionally observed. Headache and impotence or dysuria may occur rarely. Orthostatic hypotension has been reported and may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics. Skin rashes, urticaria and purpura have been reported in a few instances.

A decreased glucose tolerance evidenced by hyperglycemia and glycosuria may develop inconsistently. This condition, usually reversible on discontinuation of therapy, responds to control with antidiabetic treatment. Diabetics and those predisposed should be checked regularly.

As with other diuretic agents hypokalemia may occur (see Precautions). Hyperuricemia may be observed on occasion and acute attacks of gout have been precipitated. In cases where prolonged and significant elevation of blood uric acid concentration is considered potentially deleterious, concomitant use of a uricosuric agent is effective in reversing hyperuricemia without loss of diuretic and/or antihypertensive activity.

Idiosyncratic drug reactions such as aplastic anemia, thrombocytopenia, leukopenia, agranulocytosis, and necrotizing angiitis have occurred, but are rare.

The remote possibility of pancreatitis should be considered when epigastric pain or unexplained gastrointestinal symptoms develop after prolonged administration.

Other adverse reactions which have been reported with this general class of compounds include: jaundice, xanthopsia, paresthesia and photosensitization.

Overdosage: *Catapres (clonidine hydrochloride):* Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals abolishes all effects of Catapres overdosage.

Chlorthalidone: Symptoms of overdosage include nausea, weakness, dizziness, and disturbances of electrolyte balance. There is no specific antidote, but gastric lavage is recommended, followed by supportive treatment. Where necessary, this may include intravenous dextrose and saline with potassium administered with caution.

How Supplied: Combipres* 0.1 (Each tablet contains clonidine hydrochloride 0.1 mg + chlorthalidone 15 mg). It is available as pink, oval, single-scored compressed tablets in bottles of 100.

Combipres* 0.2 (Each tablet contains clonidine hydrochloride 0.2 mg + chlorthalidone 15 mg). It is available as blue, oval, single-scored compressed tablets in bottles of 100.

For complete details, please see full prescribing information.

Electrophysiologic and Anatomic Correlates of Sustained Ventricular Tachyarrhythmias in a Model of Chronic Myocardial Infarction

ERIC L. MICHELSON, MD
JOSEPH F. SPEAR, PhD, FACC
E. NEIL MOORE, DVM, PhD, FACC

Philadelphia, Pennsylvania

Ten healthy adult mongrel dogs were subjected to two stage occlusions of the mid or distal left anterior descending coronary artery modified by a reperfusion stage. In 9 of 10 animals studied at 3 or more days after coronary occlusion, sustained reentrant ventricular tachyarrhythmias could be reproducibly initiated or terminated, or both, using routine methods of programmed electric stimulation. Plunge electrodes were inserted at multiple subepicardial, intramyocardial and subendocardial sites from areas of normal and infarcted myocardium to evaluate electrophysiologic properties of excitability and refractoriness. With use of constant current unipolar cathodal stimulation, strength-interval curves were measured at these sites and correlated with regional histopathologic findings. In this model, infarcts were mottled, with close interspersing of normal and abnormal myocardium. Although excitability thresholds and refractoriness tended to increase within areas of infarction, marked disparities in excitability thresholds, effective and relative refractory periods and duration of relative refractory periods (relative minus effective refractory period) were observed within areas of infarction at sites only 1 to 2 mm apart anatomically. This milieu of anatomic and electrophysiologic heterogeneity is apparently sufficient to predispose to the initiation of sustained reentrant ventricular tachyarrhythmias.

Clinical and basic electrophysiologic studies[1–12] have suggested that reentry may be one of the mechanisms responsible for the susceptibility to ventricular tachyarrhythmias and ventricular fibrillation in the setting of both acute myocardial ischemia and chronic infarction.[1–12] Several investigators[13–15] have recently reported that sustained ventricular tachyarrhythmias can be reproducibly initiated in dogs 3 to 5 days after coronary arterial occlusion and reperfusion using routine methods of programmed electric stimulation. This report describes the results of detailed electrophysiologic studies in one of these models. We have evaluated regional excitability and refractoriness in this model and have correlated electrophysiologic data with histopathologic findings to characterize better those properties predisposing to inducible sustained ventricular tachyarrhythmias.

Methods

Study animals: Studies were performed on 12 healthy adult mongrel dogs weighing 8 to 16 kg. Animals were anesthetized with intravenous sodium pentobarbitol (30 mg/kg body weight) and then ventilated with room air through a cuffed pharyngeotracheal tube using a volume-cycled positive pressure respirator. Body temperature was maintained with a thermal mattress. With sterile procedures the heart was exposed through a limited (less than 4 cm) left thoracotomy at the fourth left intercostal space, the pericardium opened and a peri-

cardial sling created. In 10 animals the left anterior descending coronary artery was occluded by the Harris two stage procedure: partial occlusion for 30 minutes and then complete occlusion.[16] In four of these animals the left anterior descending coronary was occluded distal to the first large diagonal branch 1 to 2 cm from its origin; in one animal distal to the second of three diagonal branches; and in the other five animals the left coronary artery was occluded distal to all diagonal branches at the termination of its course, near the left ventricular apex. In each of these 10 animals ligatures were then released 2 hours after complete occlusion.[13–15] Reestablishment of pulsatile arterial blood flow distal to the site of occlusion was evident in each case. Five minutes before release of the ligatures; the animals were pretreated with a bolus injection of intravenous lidocaine (2 mg/kg) and 5 minutes after ligature release with a second lidocaine bolus dose (1 mg/kg). There were no episodes of ventricular fibrillation associated with ligature release in animals pretreated in this manner. Two sham-operated control animals underwent identical procedures except that ligatures were placed nonocclusively.

Experimental procedures: The chests were closed and routine postoperative care was administered including prophylactic antibiotic therapy (with either penicillin or cefazolin plus streptomycin, both intramuscularly). At 3 to 8 days after initial occlusion, when the animals were in otherwise clinically stable condition and the accelerated ventricular arrhythmias of the first 24 to 48 hours had subsided, they were anesthetized with sodium pentobarbital (10 mg/kg) plus diazepam (1 to 2 mg/kg), each intravenously. Ventilation and body temperature were maintained as before, and the heart was exposed through a left lateral thoracotomy. In selected experiments arterial pressure was monitored by cannulation of the carotid or femoral artery. With use of 23 gauge needles, Teflon®-coated stainless steel plunge (hook) wire electrodes (0.10 mm in diameter) were placed in multiple subepicardial, intramyocardial and subendocardial sites within areas of both normal and infarcted myocardium. The plunge electrodes were insulated except at the tip. Either unipolar or bipolar electrograms, or both, were recorded at 5 to 15 sites per animal at filter settings of 40 to 1,000 hertz. Routine methods of programmed electric stimulation (see later) were performed using unipolar cathodal stimulation to determine whether sustained ventricular tachyarrhythmias could be induced. Rectangular cathodal current pulses of 2 ms duration were delivered by a constant current source that was continuously variable from 0 to 10 mA. The indifferent anode was a stainless steel rib spreader having an approximately 8 cm^2 surface in contact with the chest wall. Programmed electric stimulation was performed using a custom-designed digital stimulator.

Protocol of programmed electric stimulation: To evaluate the propensity to sustained ventricular tachyarrhythmias, ventricular extrastimuli were introduced during ventricular pacing using unipolar cathodal stimulation. Both basic drive pacing and extrastimuli were applied at the same ventricular site using constant current pulses twice diastolic threshold. This propensity to arrhythmogenesis was evaluated at multiple sites in each animal because the site of stimulation influenced susceptibility. Scanning of diastole was initiated with the introduction of a single ventricular extrastimulus after eight paced beats, at a basic cycle length of 300 ms. In animals with less than 1:1 retrograde ventriculoatrial conduction during drive ventricular pacing, left atrial pacing was done simultaneously during the drive pacing to prevent interference by supraventricular beats. If a sustained ventricular tachyarrhythmia was not elicited, double and, if necessary, triple ventricular extrastimuli were then introduced during ventricular pacing. In addition, rapid ventricular pacing for 15 to 30 seconds (cycle lengths 200 ms or less) was also used to attempt initiation of a sustained ventricular tachyarrhythmia if triple ventricular extrastimuli were not successful. After ventricular tachyarrhythmia was induced, random ventricular pacing or programmed single or double ventricular extrastimuli were introduced in an attempt to terminate ventricular tachycardia. In animals with ventricular tachyarrhythmia causing rapid hemodynamic deterioration, direct countershock (10 to 40 watt seconds) was applied if a burst of rapid ventricular pacing was not successful in terminating the arrhythmia. "Sustained" was defined as more than 1 minute of ventricular tachycardia or nonself-terminating ventricular flutter or fibrillation.

Measurements of excitability and refractoriness: With use of unipolar cathodal stimulation, thresholds for excitability were determined at each electrode site. Strength-interval curves were constructed by the following method[17–19]: An extrastimulus (S_2) was introduced in late diastole at the minimal milliamperage for eliciting a ventricular response (V_2) after eight paced beats at a basic cycle length of 300 ms. The current for the paced beats was held constant throughout the determination at twice the minimal diastolic threshold for excitability. The coupling interval of S_2 was then decreased in 1 to 2 ms steps until S_2 failed to elicit a V_2. When S_2 failed to elicit a V_2 the milliamperage of S_2 was then increased incrementally until a V_2 was elicited, and the coupling interval decreased until S_2 again failed to elicit a V_2. This sequence was repeated until an effective refractory period was reached or until a maximum of 10 mA.

The effective refractory period, therefore, was defined as the longest S_1–S_2 interval failing to elicit a V_2. In order to verify their configuration and reproducibility, strength-interval curves were also constructed at representative sites using a second method[17–19]: The minimal milliamperage required to elicit a response at each of multiple coupling intervals in diastole was determined independently rather than shortening the coupling interval to refractoriness at each given current intensity. This was done by first setting the coupling interval for S_2 then increasing the current from zero to the minimal current required for eliciting a V_2 at that coupling interval.

The relative refractory period was defined as the longest coupling interval along the strength-interval curve at which the current required to evoke a response (V_2) increased above the diastolic excitability threshold by greater than 0.025 mA for a 1 ms change in coupling interval. This criterion was chosen to provide adequate resolution and consistency in determing the longest coupling interval that showed an increased threshold current requirement for stimulation. The duration of the relative refractory period was defined as the difference between the relative refractory period and the effective refractory period (that is, the relative minus the effective refractory period).

Properties of (1) threshold for excitability (that is, minimal current eliciting a V_2 at any long coupling interval); (2) effective refractory period; (3) relative refractory period; and (4) the duration of the relative refractory period were determined for multiple subendocardial, intramyocardial and subepicardial sites from within the area of infarction and from multiple sites within normal control areas in each animal. Electrophysiologic properties at multiple sites were reevaluated throughout the study, both before and after all interventions (including countershock) to validate the stability of measurements at different sites over time. Unipolar cathodal stimulation was done in the present study specifically to avoid the complex curves characteristic of anodal and bipolar stimulation.[17–19]

After electrophysiologic studies were completed the animals were killed with plunge electrodes in place. Plunge electrode positions were confirmed at postmortem examination. Infarct size was estimated by inspection using 1 to 2 mm thick slices of myocardium. Hearts were then thin-sectioned and histopathologic staining was performed using either hematoxylin-eosin, trichrome or nitroblue tetrazolium. Histopathologic findings were then correlated with local electrophysiologic properties.

All experiments conformed with the "Guiding Principles in the Care of Animals" approved by the Council of the American Physiological Society and with the Animal Care Policy of the University of Pennsylvania.

Statistics: Electrophysiologic data were analyzed using *t* tests of paired samples. Data from areas of infarcted myocardium were compared in each case with measurements from the normal (control) areas in the same animal, and the differences between the means of paired samples were determined for the excitability thresholds, effective refractory periods, relative refractory periods and the duration of relative refractory periods. Pooled data were also analyzed using a comparison of means.

Results

With use of routine methods of programmed electric stimulation,[3,6,10-12] 9 of 10 animals with experimental coronary occlusion had reproducibly sustained ventricular tachyarrhythmias. During ventricular pacing at a basic cycle length of 300 ms, 4 animals manifested ventricular tachycardia (cycle length 150 ms or greater), ventricular flutter (cycle length 90 to 130 ms) or ventricular fibrillation, or both, after a single ventricular extrastimulus (Fig. 1). In three animals two ventricular extrastimuli were required, and in two animals three ventricular extrastimuli were necessary to induce sustained ventricular tachyarrhythmias. In two sham-operated control animals and in one animal with a distal occlusion of the left anterior decending coronary artery no reproducible arrhythmias were induced by either single or multiple ventricular extrastimuli or by rapid ventricular pacing at a cycle length of less than 200 ms.

In the four animals with inducible sustained ventricular tachycardia (cycle lengths of 150 to 280 ms), this arrhythmia was tolerated hemodynamically and could be terminated by either programmed ventricular stimulation (two animals) or with rapid ventricular pacing (two animals).

Electrophysiologic data (Table I): Excitability thresholds, effective refractory periods, relative refractory periods and duration of relative refractory periods were measured in 10 study animals at a total of 43 normal left ventricular sites including 19 subepicardial, 14 intramyocardial and 10 subendocardial sites. Normal (control) sites were chosen from myocardium in the distribution of nonoccluded vessels at 2 or more cm from any apparent area of infarction in the in vivo beating heart. Sites within areas designated as "area of infarction" were those in the direct distribution of occluded vessels. These areas were variously akinetic and discolored and they had a wood-like indurated consistency to palpation. Clearly demarcated areas of infarction were not always apparent on examination of the in vivo beating heart.

Although within individual animals the ranges of excitability threshold, effective refractory period, relative refractory period and duration of relative refractory period measurements at different normal sites were relatively narrow, greater variations were observed when the electrophysiologic data from normal sites were

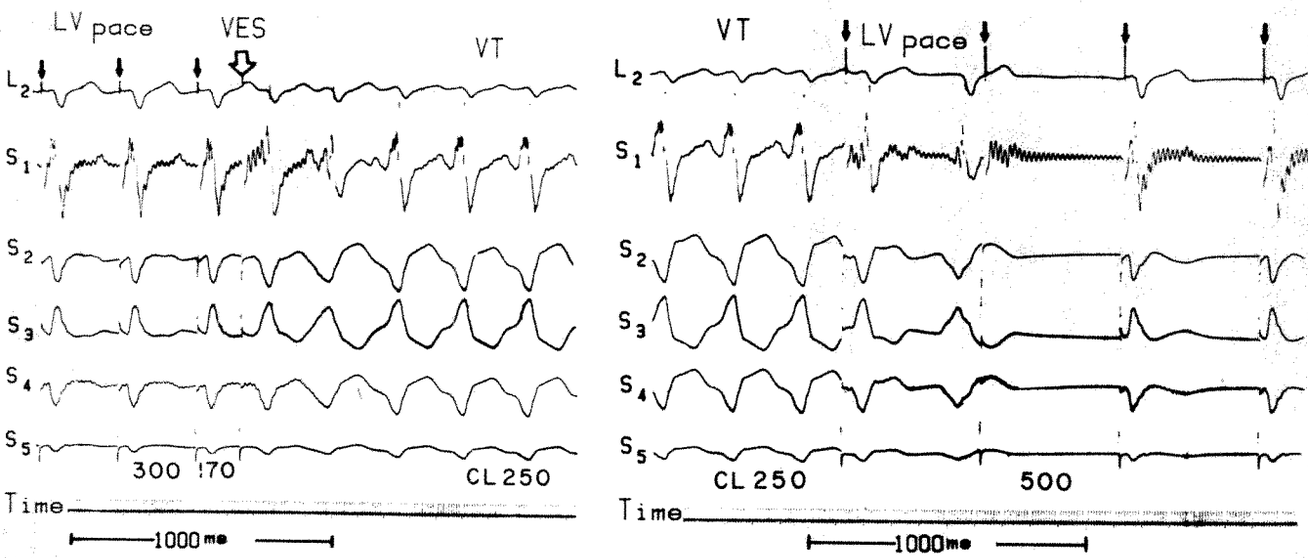

FIGURE 1. Analog records demonstrating the initiation (**left**) and termination (**right**) of sustained ventricular tachycardia (VT). **Left,** surface electrocardiographic lead II (L_2) and unipolar plunge electrode recordings from multiple left ventricular sites ($S_1 - S_5$) from within the area of infarction are displayed as well as time lines. At a left ventricular pacing cycle length of 300 ms (LV pace, **arrows**) a single ventricular extrastimulus (VES) at a coupling interval of 170 ms reproducibly initiated sustained ventricular tachycardia at a cycle length (CL) of 250 ms. **Right,** 1 minute after the records in the **left panel** were obtained, random left ventricular pacing (**arrows**) was begun at a cycle length of 500 ms and the ventricular tachycardia was terminated.

TABLE I

Summary of Electrophysiologic Data (range and mean ± standard deviation)

	no.	ET(mA)	ERP (ms)	RRP (ms)	D-RRP (ms)
Normal sites					
Subendocardial	19	0.02–0.12; 0.07 ± 0.03	111–148; 130 ± 12	124–166; 147 ± 13	5–25; 17 ± 5
Intramyocardial	14	0.03–0.14; 0.06 ± 0.03	111–153; 132 ± 14	125–168; 150 ± 12	12–23; 18 ± 4
Subepicardial	10	0.04–0.24; 0.09 ± 0.06	109–152; 137 ± 12	122–170; 154 ± 15	6–24; 17 ± 7
Total	43	0.02–0.24; 0.07 ± 0.04	109–153; 132 ± 13	122–170; 149 ± 13	5–25; 17 ± 5

* Does not include completely inexcitable sites. D-RRP = duration of refractory period = (RRP minus ERP); ERP = effective refractory period; ET = threshold for excitability; n = number of sites; RRP = relative refractory period.

compared among different animals. However, these differences were taken into account in our analysis of electrophysiologic data by using *t* tests for paired samples within individual animals (for example, normal subendocardium versus infarct subendocardium). Pooled data are also summarized in Table I. There were no significant differences ($p > 0.10$) observed in any of the variables of excitability or refractoriness in comparing normal sites from the subepicardial, intramyocardial or subendocardial layers.

Table I also lists in detail the ranges and mean values for the excitability thresholds and refractory period measurements for 38 sites from within the areas of infarction in the 10 study animals. Significant increases in excitability thresholds and refractoriness were observed when sites within areas of infarction were compared with normal control sites. Data were analyzed separately for all subendocardial, intramyocardial and subepicardial sites in each animal. These differences were greatest for measurements of effective refractory periods, relative refractory periods and duration of relative refractory periods but were less consistently abnormal with respect to determinations of minimal thresholds for excitability. In each of the nine animals with inducible ventricular tachyarrhythmias there was marked heterogeneity of the electrophysiologic data obtained from different sites within the area of infarction. This heterogeneity was reflected within each animal by the wide range of refractory period and excitability threshold measurements, and statistically by large coefficients of variation (that is, large standard deviations compared with their means = standard deviation/mean × 100) for the values recorded from the areas of infarction. In addition, in individual animals sites were studied that were completely inexcitable. In the one animal that had undergone the occlusion procedure but had no inducible sustained ventricular tachyarrhythmias this heterogeneity of electrophysiologic properties was not observed.

Although a comparison of means confirmed significant differences for electrophysiologic data from areas of infarction compared with normal control areas, there was considerable overlap in the measurements from normal and infarcted areas (Table I). This electrophysiologic heterogeneity was apparent within all three "layers": subendocardium, intramyocardium and subepicardium. However, the degree of heterogeneity among these different layers was not distinguishable statistically.

Anatomic findings (histopathology): In two sham-operated control animals local epicardial tissue trauma was evident adjacent to the sites where the nonocclusive sutures had been placed temporarily. No other injury was apparent. In each of the 10 animals subjected to occlusion and reperfusion of the left anterior descending coronary artery, "mottled" infarction was present with close interspersing of areas of normal and abnormal myocardium. In general, there was a tendency to mild (1 mm or less) subepicardial sparing but there was no consistent gradient of injury from one layer to the next. Histopathologic staining and microscopic examination confirmed marked interspersing of normal, abnormal, necrotic and hemorrhagic myocardium; mononuclear cell infiltration and increased trichrome-connective tissue staining were consistent with subacute and chronic tissue injury (Fig. 2). Increased interstitial hemorrhage and intracellular, granular calcium deposition were also observed, typical of re-

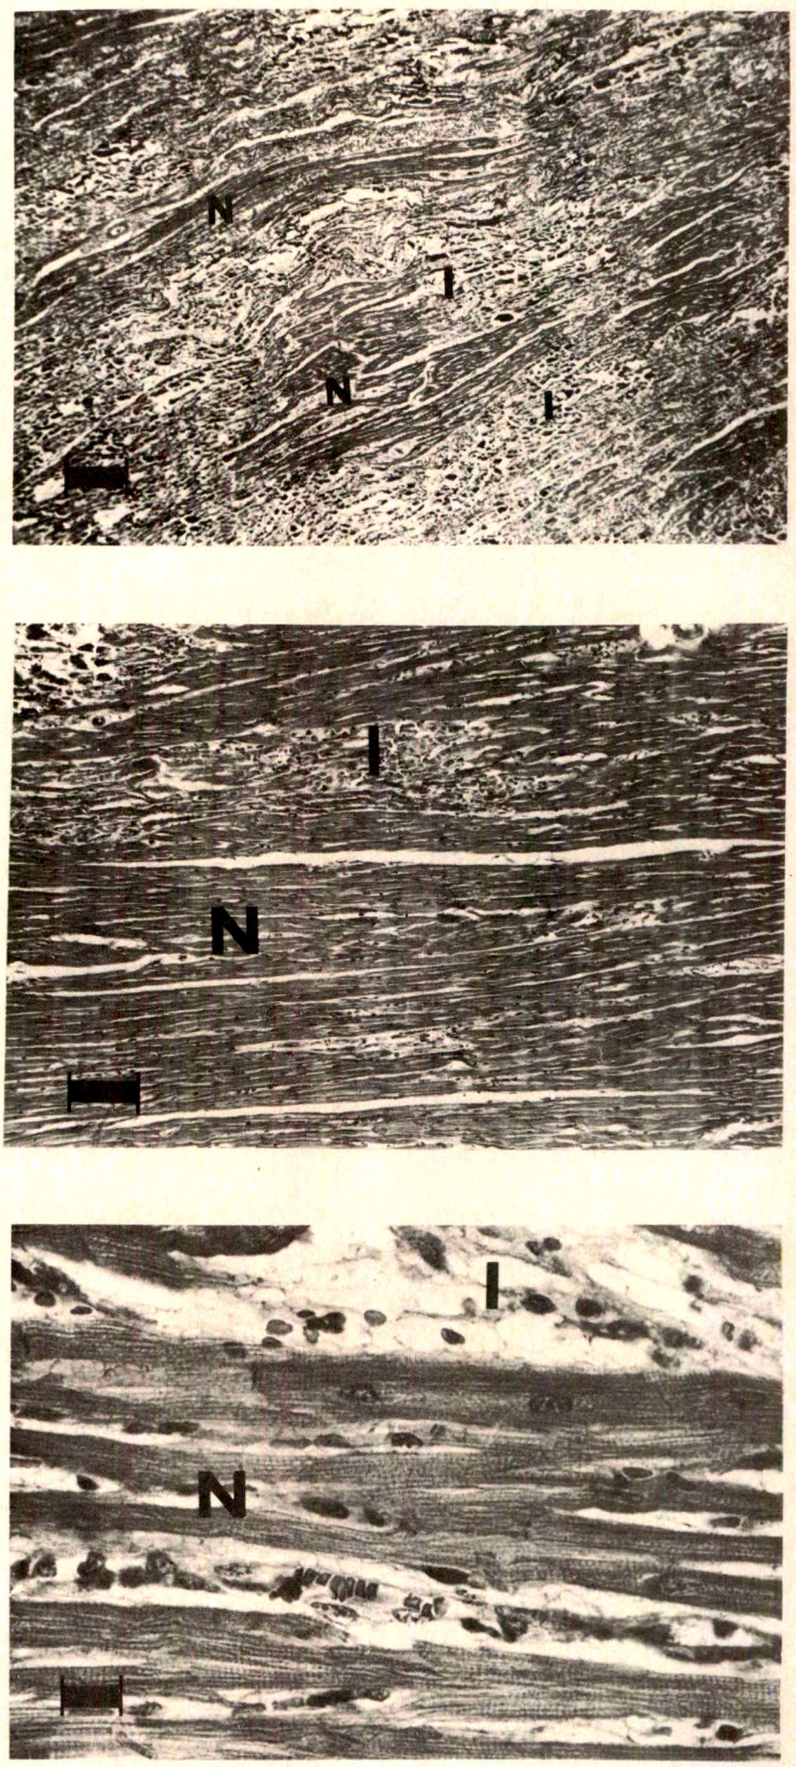

FIGURE 2. Histopathologic findings. Photomicrographs of hematoxylin-eosin–stained sections from a 7 day old infarct. **Top,** an intramyocardial segment demonstrating marked interspersing of normal (N) and abnormal (I) myocardium, with islands of apparently normal myocardium surviving even within areas of marked necrosis. **Horizontal bar** indicates 300 μ. (×30, reduced by 38 percent.) **Center,** another intramyocardial segment demonstrating less dense mottling, but with islands of infarcted necrotic myocardium (I) suspended within areas of otherwise normal myocardium (N). **Horizontal bar** indicates 200 μ. (×50, reduced by 38 percent.) **Bottom,** an island of normal (N) myocardium from within an area of otherwise dense infarction (I), similar to that in **top panel.** Note the well defined membranes, intercalated discs, normal striations and nuclei. **Horizontal bar** indicates 40 μ. (×400, reduced by 38 percent.)

perfusion injury. Of note, islands of normal tissue, 1 to 2 mm^2, were often architecturally intact even within areas of the most dense infarction. In each of the 10 animals subjected to coronary occlusion and in both sham-operated control animals, sites designated as normal in vivo were confirmed histopathologically.

Electrophysiologic correlates: Electrophysiologic properties determined in normal control anatomic areas were normal in each case. Electrophysiologic properties evaluated in areas within the infarction but later determined to be normal anatomically were also normal. Electrophysiologic measurements from anatomically abnormal and necrotic areas only 1 to 2 mm distant were often markedly abnormal (Fig. 3). Because the mottled islands were often less than a millimeter in diameter, more precise correlation of histopathologic findings to plunge electrode positions was not possible. In three animals there was no gross evidence of infarction in vivo 96 hours after distal left coronary artery occlusion. In two of these animals sustained ventricular tachyarrhythmias were induced reproducibly with single or double ventricular extrastimuli; postmortem examination revealed multiple 1 to 3 mm^2 islands of abnormal tissue interspersed within an area of 1 cm^2 in one animal and within an area of 1.5 cm^2 in the other. In the third animal there were no inducible ventricular arrhythmias; postmortem examination revealed 5 punctate necrotic areas, each approximately 1 mm^2, dispersed over a 6 cm^2 area in the distribution of the occluded left coronary artery. Apparently a large circumflex marginal vessel coursing to the apex and anastomosing with the distal left anterior descending coronary was sufficient to account for the low density of infarcted myocardium in the area distal to the occlusion.

Consistently, in each animal studied, all electrophysiologic measurements of excitability and refractoriness were remarkably reproducible and similar throughout the study using either technique of determining strength-interval curves (see Methods). Refractory periods were reproducible to within 1 to 2 ms after hours of study and in several animals measurements remained consistent even after multiple defi-

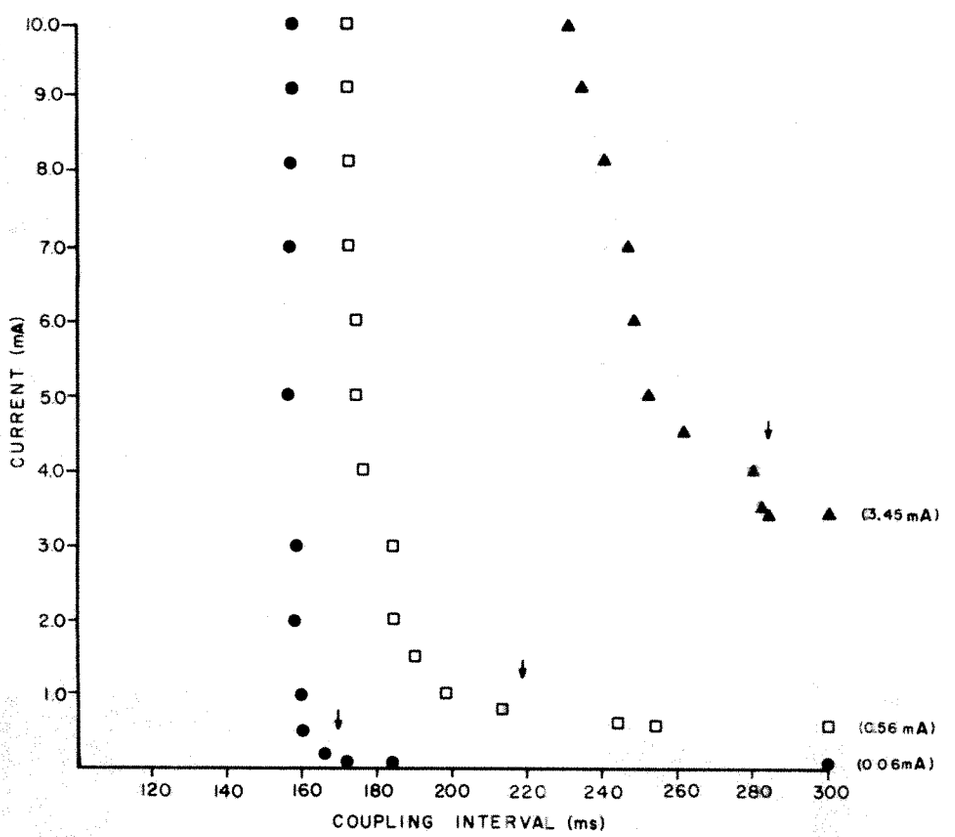

FIGURE 3. Strength-interval curves from normal and infarcted myocardium. Refractoriness (coupling interval) in ms is plotted versus current (in mA) required to elicit a response at that coupling interval. Curves were constructed as described in the text. The curve derived from measurements at site 1 (**closed circles**) was typical of normal myocardium. Site 1 was intramyocardial in the distribution of a nonoccluded vessel. At this site the excitability threshold is 0.06 mA, the effective refractory period 156 ms, the relative refractory period 172 ms (**arrow**) and duration of relative refractory period 16 ms. Site 2 (**open squares**) was intramyocardial from within an area of infarction. All measurements of excitability were mildly abnormal: excitability threshold 0.56 mA; effective refractory period 172 ms, relative refractory period 220 ms (**arrow**) and duration of relative refractory period 48 ms. Site 3 (**closed triangles**) was intramyocardial from within an area of infarction only 1 to 2 mm distant from site 2 and electrophysiologic measurements were markedly abnormal: excitability threshold 3.45 mA; effective refractory period 230 ms, relative refractory period 283 ms (**arrow**) and duration of relative refractory period 53 ms. Note that refractoriness at twice the minimal diastolic excitability threshold would intersect the strength-interval curve along that portion where small changes in current would result in relatively large changes in measurements of refractoriness (coupling interval).

brillations. Measurements of thresholds of excitability were stable to within ± 0.02 mA. In addition, one animal was studied serially on days 3, 5, 6 and 8 after occlusion using one right and one left ventricular sewn-on epicardial pentapolar plaque electrode. With use of these limited sites, refractory period measurements remained stable to within 5 ms as did the coupling intervals required for initiation of ventricular tachyarrhythmias. In all other animals with inducible ventricular tachyarrhythmias, modes of initiation remained stable during the hours of study.

Discussion

This study presents detailed in vivo electrophysiologic data in a long-term dog model susceptible to sustained ventricular tachyarrhythmias. Nine of 10 animals surviving two stage occlusion and then reperfusion of the mid or distal left anterior descending coronary artery had reproducible, inducible, sustained ventricular tachyarrhythmias using routine methods of programmed electric stimulation when studied 3 to 8 days after occlusion. Previously reported experimental and clinical studies have provided strong evidence that the ventricular arrhythmias inducible by these methods of programmed electric stimulation are reentrant in mechanism and are less likely to be related to triggered automaticity or to other mechanisms.[3,5–12,20,21]

Electrophysiologic and histologic correlates: Extensive electrophysiologic data were obtained in vivo in this model of long-term infarction. Most striking was the marked heterogeneity of measurements of excitability and refractoriness from sites in close proximity within areas of infarction. Sites indistinguishable from normal and others mildly, moderately and severely abnormal were juxtaposed within millimeters of each other. Strength-interval curves were constructed and revealed marked prolongation in relative refractory period and in the duration of relative refractory period measurements, even at sites where effective refractory period and excitability threshold determinations were normal or only mildly abnormal. Postmortem histopathologic examination revealed an anatomic basis for these greatly disparate electrophysiologic properties within areas of infarction. Infarcts were mottled with close interspersing of normal and abnormal myocardium throughout the subepicardial, intramyocardial and subendocardial layers with only mild subepicardial sparing.

The inflections and prolongation in relative refractory periods and duration of relative refractory periods in the abnormal strength-interval curves (Fig. 3) may be explained by a recruitment phenomenon. In normal muscle where excitability and refractoriness are more homogeneous in a given region, strength-interval curves determined by extracellular stimulation techniques would be expected to reflect this homogeneity. In the mottled milieu of the infarcts, as current intensity is increased during determination of strength-interval curves, tissue may be brought to threshold at a distance from the electrode site with properties of excitability and refractoriness different from those near the electrode. The strength-interval curve would reflect this recruitment by exhibiting inflections and widening of the curve between the effective and relative refractory periods. Further analysis of the complex strength-interval curves constructed from abnormal areas also suggests possible limitations in interpreting data obtained only at twice diastolic excitability threshold (Fig. 3).

Facilitation of sustained ventricular tachyarrhythmias: The relation between the abnormal strength-interval curves and the tachyarrhythmias in these animals is less clear. Excitability determined by extracellular stimulation represents a minimal value for a mass of tissue in the region of the electrode. This value is determined not only by the intrinsic excitability of cells but also by the density of depolarizing current across cell membranes, which is a function of their distance from the electrode as well as of the tissue conductivity. Very little can be deduced about how an impulse will conduct through an area by analyzing the extracellular strength-interval curves obtained from that area. However, the marked disparity among effective refractory periods obtained in close proximity does suggest that in relatively small areas of myocardium a premature beat may conduct in one region and be blocked in an adjacent region. This would be a prerequisite for the occurrence of "microreentry." The prolongation of the relative refractory period and increased excitability threshold in abnormal regions may be reflecting a decreased intrinsic excitability of cells in these areas at this time. Because cell excitability is one of the determinants of conduction velocity there may be local slowing of conduction velocity in these areas that would also predispose to "microreentry" [22,23]

Our data verify that in this model heterogeneous histologic findings are accompanied by heterogeneous electrophysiologic properties and that these hearts are susceptible to sustained ventricular tachyarrhythmias. In the one animal with no inducible ventricular tachyarrhythmias, there were only five punctate discrete areas, each only 1 mm^2, dispersed over an area 6 cm^2 in the distribution of the occluded vessel; no abnormalities of excitability or refractoriness were detected in vivo using multiple plunge electrodes. Had one of these punctate necrotic areas been entered fortuitously, undoubtedly some abnormalities would have been observed; however, this milieu was apparently not sufficient for the occurrence of inducible ventricular tachyarrhythmias. In two other animals the total area of abnormal myocardium was similarly less than 1 cm^2, but in each case these abnormal areas were compressed to within a total mottled area of only 2 cm^2 and therefore the density of abnormal tissue was greater, as evidenced by histopathologic examination. This increased density of abnormal tissue was apparently sufficient to facilitate sustained ventricular tachyarrhythmias.

Advantages of present model of canine myocardial infarction: Previous investigators[2,8,24–26] have also studied acute and chronic models of occlusion and reperfusion and have correlated abnormalities in electrophysiologic properties with the occurrence of arrhythmias characteristic of reentry. In the present

model, because of its stability, we were able to evaluate excitability and refractoriness at multiple sites and correlate these with the histologic features. This model apparently provides the appropriate milieu for inducible sustained reentrant ventricular tachyarrhythmias.[13–15] The histologic findings are also similar to those described by Reimer et al.[27] after temporary circumflex coronary arterial occlusion. The degree of mottling with close interspersing of normal, abnormal and hemorrhagic myocardium within areas of infarction in this model is much more pronounced than that occurring after routine occlusion techniques. Presumably, the hyperemic response to complete release of occlusion facilitates diffuse mottling within areas of infarction. Remarkably, areas of ischemic damage less than 1 cm^2 appear sufficient for the occurrence of sustained arrhythmias.

This model has additional advantages: the infarctions produced are small; therefore, the animals remain in clinically stable condition and may tolerate ventricular tachyarrhythmias (for example, cycle length 150 ms) without rapid hemodynamic deterioration. There is remarkable stability of electrophysiologic measurements over the course of hours and even after defibrillation in this model. In addition, preliminary studies have suggested the stability of the model over a course of days. Most important, sustained ventricular tachyarrhythmias are inducible in this model with use of the same techniques of programmed electric stimulation practiced in the clinical laboratory. Further investigation is required to determine for how many days, weeks or even longer periods these markedly heterogeneous electrophysiologic and anatomic abnormalities persist and for how long the susceptibility to inducible sustained ventricular tachyarrhythmias persists. This model should also be suitable for the further evaluation of both mechanisms of arrhythmia and the effects of potential therapeutic regimens.[14]

Scanning Electron Microscopy After Coronary Transluminal Angioplasty of Normal Canine Coronary Arteries

RICHARD C. PASTERNAK, MD
KENNETH L. BAUGHMAN, MD
JOHN T. FALLON, MD, PhD
PETER C. BLOCK, MD, FACC

Boston, Massachusetts

Percutaneous coronary transluminal angioplasty is currently being proposed as a possible treatment for some patients with significant coronary arterial lesions. In this study scanning electron microscopy was used to assess the morphologic changes caused by the angioplasty balloon catheter in normal canine coronary arteries. Balloon inflation uniformly caused endothelial denudation with virtually immediate dense platelet adhesion to the subendothelial matrix. This platelet adhesion was unaffected by pretreatment with aspirin (35 mg/kg body weight) or heparin (2,000 units). However, intravenous administration of low molecular weight dextran almost completely prevented platelet adhesion to the exposed subendothelial connective tissues.

It is concluded that even in normal canine coronary arteries (1) loss of endothelium is seen after transluminal angioplasty; (2) this endothelial damage stimulates platelet adhesion and thrombus formation; and (3) the immediate layering of platelets can be prevented by administration of low molecular weight dextran.

Percutaneous coronary transluminal angioplasty had been introduced as a possible treatment for selected patients with partially stenotic coronary arterial lesions.[1] The technique requires a specially designed polyvinyl chloride, inflatable but nondistensible, balloon-tipped catheter that can be used to dilate discrete coronary arterial narrowings. Thus far, little morphologic information is available on the effects of this angioplasty catheter on the arterial wall.

Scanning electron microscopy has been used extensively in the study of various forms of damage to vascular endothelium. Endothelial injury has been induced by diamond mesh,[2] vibrating catheter,[3] scalpel blade,[4] vasospasm,[5] external ligatures or electric stimulation,[6] and most often by a balloon-tipped catheter.[7–9] Rabbit aorta,[2–4,7,8] feline basilar artery,[5] swine coronary artery[9] and, in a preliminary study, canine coronary endothelium[6] have been used for study in various models. In this report we describe in detail the findings of a study on the endothelial damage induced by coronary transluminal angioplasty in normal canine coronary arteries. In addition, we report on the effects of several antithrombotic regiments used during angioplasty.

Methods

Experimental procedure: Eleven mongrel dogs weighing 20 to 30 kg were anesthetized with sodium pentobarbital. The chest was opened through a left thoracotomy incision and the heart suspended in a pericardial cradle. A single lumen 3 mm Gruntzig balloon angioplasty catheter (Schneider Corporation, Zurich, Switzerland) was inserted into a diagonal branch of the left anterior descending coronary artery. The angioplasty catheter, with balloon tip deflated, was passed retrograde into the main lumen of the left anterior descending coronary artery. The balloon was rapidly inflated (Fig. 1, top), full inflation was maintained for 10 seconds, and then the balloon was rapidly deflated. Care was

From the Department of Medicine (Cardiac Unit) and Pathology, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts. This study was supported in part by Grant H1 18714 from the National Institutes of Health, Bethesda, Maryland. Manuscript received July 10, 1979; revised manuscript received October 30, 1979, accepted October 31, 1979.

taken not to move the catheter during balloon inflation. The dimension of the inflated balloon (3 mm) approximated the coronary arterial luminal diameter in all dogs. In most animals slight distension of the artery was apparent externally. After balloon deflation the catheter was removed, and after 15 minutes the proximal left anterior descending coronary artery was cannulated and immediately perfused with cacodylate-buffered 2 percent gluteraldehyde fixative at a physiologic pressure of 100 mm Hg (Fig. 1, bottom). Perfusion was continued for 10 minutes. Figure 2 shows the Gruntzig balloon catheter and the apparatus used for inflation of the balloon and for measuring inflation pressure. For this study the system was filled with saline solution, and the balloon was inflated to 60 lb in^2 (4 atmospheres) using a hand-held syringe.

Scanning electron microscopy: All hearts fibrillated 15 to 45 seconds after the initiation of coronary perfusion. Segments of coronary artery were then dissected from the intact preparation and placed in 20 cc of fixative for 24 hours. The entire portion of artery from the site of cannulation (proximally) to the tie on the left anterior descending diagonal branch (distally) was included in this dissection. (Fig. 1). Also included was 2 to 3 cm of the distal left anterior descending artery, just beyond the takeoff of the diagonal branch. Further preparation of the specimen for scanning electron microscopy

included postfixation in osmium tetroxide, dehydration with acetone and critical point drying in liquid carbon dioxide. The specimens were cut longitudinally, mounted on stubs and coated with gold-palladium. Vessels were viewed in an AMR 1400 scanning electron microscope. The entire endothelial surface of vessels dissected from the intact preparation was scanned.

Twenty-four hour study: In two of the 11 dogs, immediately after angioplasty and balloon removal, the chest was closed and the dogs were allowed to recover from anesthesia. Mild sedation was maintained with intramuscular injections of morphine sulfate. Twenty-four hours later the animals were reanesthetized, the chest opened and the coronary arteries perfused and prepared as previously described.

Antithrombotic agents: In an attempt to evaluate thrombus formation on the intima in the area of dilatation, antithrombogenic agents were administered to 7 of 11 dogs (Table I). Thirty-five mg/kg of aspirin was administered intravenously to two dogs 1 hour before the experiment; heparin, 2,000 units, was administered intravenously to two dogs 10 minutes before the experiment; and 0.5 liter of low molecular weight dextran was given intravenously to three dogs 4 hours before the experiment (one of these was studied at 24 hours).

Results

The effects of balloon angioplasty were consistent throughout all specimens in treated and untreated animals. Pharmacologic agents produced identical results in similarly treated dogs but varying effects among differently treated animals, as described later.

Untreated animals: Balloon dilatation consistently produced extensive endothelial denudation in the segment where the balloon was inflated. Distinct margins were present at branch vessels not entered by the balloon catheter, and in the left anterior descending artery above and below the site of balloon inflation (Fig. 3). At these margins degenerating cells were visible, some with one end of the cell still adherent to the subendothelium and the others apparently torn free within the denuded areas of intima. A carpet of platelets, scattered red blood cells and areas of fibrin thrombus were seen deposited on the subendothelial connective tissue, and only small patchy islands of intact endothelium were present. The degree of subendothelial damage was variable, some preparations showing disruption of the subendothelial matrix as well. However, through and through tears or medial dissections were not seen in any preparation. Outside the dilated area of the left anterior descending artery or in branch vessels, the endothelium remained intact and adherent platelets were absent. Therefore, damage was confined to the area of balloon inflation.

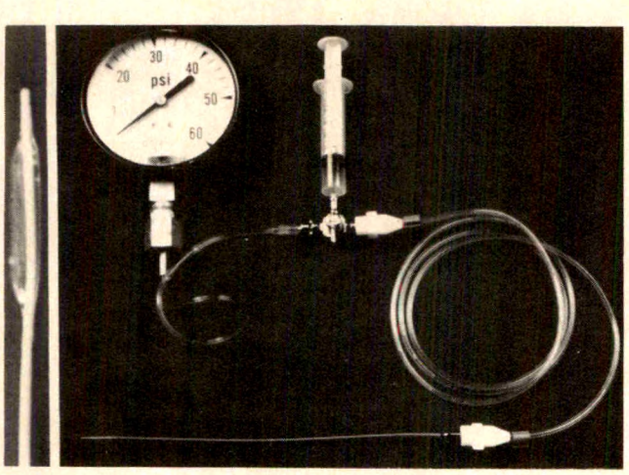

FIGURE 2. Tip of inflated Gruntzig balloon catheter (**left**). Balloon inflation system with manometer, plastic syringe, Gruntzig balloon catheter and connecting tubing (**right**).

Aspirin therapy: The intima was also severely damaged in the dogs treated with aspirin. Endothelial denudation with platelet adhesion and fibrin thrombus formation were present (Fig. 4). Although the density of adherent platelets appeared slightly less than in the untreated vessels, the pattern of deposition could not readily be distinguished from that seen in the untreated vessels.

Heparin therapy: Fibrin thrombus formation was not present in areas of endothelial damage in the dogs treated with heparin. However, dense platelet adhesion did occur (Fig. 5).

Dextran therapy: Low molecular weight dextran dramatically reduced platelet adhesion to the denuded subendothelial connective tissue in the animals studied acutely (Fig. 6). In areas of disrupted intima, scattered red blood cells and fibrin strands were present, but platelets were rare or absent. These findings were consistent throughout the dilated segment of the coronary arteries of dogs treated with dextran and studied immediately thereafter.

Twenty-four hour studies: In the animals studied 24 hours after angioplasty, damaged endothelium and platelet deposition were also apparent and the appearance was similar to the untreated dogs studied acutely. Although only one animal was treated with dextran, and the results are considered preliminary, pretreatment with dextran did not appear to prevent platelet adhesion 24 hours later. However, the morphologic features of the platelets differed from those of the early studies. Specifically, various degrees of platelet metamorphosis were noted (Fig. 7).

The endothelium is absent in the main left anterior descending artery where angioplasty was performed and the intima is covered by platelet and fibrin thrombus, whereas the endothelium of the branch vessel is intact and no thrombus is present (×100). **B**, view of border between denuded and intact endothelium seen in **A** (marked by the **white circle** in **A**), revealing a normal endothelial pattern with distinct intercellular margins and protruding central nuclei in the lower portion, contrasting with the exposed subendothelial matrix and adherent platelets present in the upper portion (×490). **C**, high power view of the border zone from **B** (marked by the **white circle** in **B**). Clearly shown are degenerating endothelial cells (DE) interdigitating with intact endothelial cells and a denuded area (**right**) covered by platelets (P) in various stages of metamorphosis (×2,000, reduced by 4 percent.)

Discussion

Scanning electron microscopy and endothelial damage: This study describes in detail the application of an in vivo canine model for the study of coronary endothelium by scanning electron microscopy. Scanning electron microscopy of injured endothelium has previously been used for the study of the subendothelium and thrombosis.[10] Models using rabbit aorta have been widely employed, and extensive data on platelet-endothelial interactions and the effect of antiplatelet agents have accumulated use of this model.[4,7,8,10–13] Scanning electron microscopy has also been used to observe in situ atherosclerosis[14] and endothelial repair.[3] A preliminary report[6] has appeared noting the effects of coronary constriction on endothelial cells using a model similar to ours. In all models used, the endothelium was easily damaged and the first morphologic consequence of this damage is the laying down of a platelet carpet on the exposed subendothelial connective tissue.[15] It is not surprising, therefore, that balloon angioplasty causes endothelial denudation and subsequent extensive platelet adhesion to the exposed surface. The model described is useful for making these direct observations, and conceivably may be applied to other potential forms of coronary endothelial damage.

Effects of coronary angioplasty: The long-term consequences of endothelial damage induced by balloon angioplasty are unknown. In rabbit aorta similarly induced endothelial denudation has been used to produce atherosclerotic lesions.[9,16] The possibility of accelerated atherosclerosis after coronary transluminal angioplasty must therefore be considered.

We have studied the effects of angioplasty on atherosclerotic lesions of rabbit aorta.[17] Endothelial denudation and platelet deposition were also observed. In

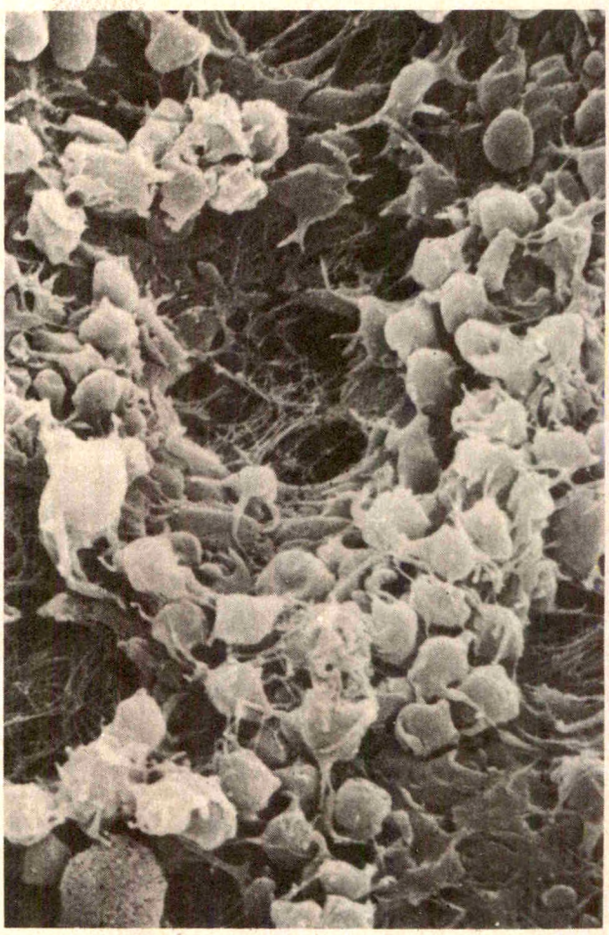

FIGURE 4. Scanning electron micrograph from the balloon-inflated area of the left anterior descending coronary artery in a dog pretreated with aspirin, showing platelet adhesion to a dense fibrin meshwork with entrapped platelets overlying a denuded area of endothelium (×3900).

FIGURE 5. Scanning electron micrograph of the left anterior descending coronary artery from a dog treated with heparin before angioplasty, revealing a partially intact endothelium (E) in the lower portion and a denuded area (where balloon was inflated) covered by a layer of platelets in the upper portion. No fibrin strands are evident. (×1,200, reduced by 4 percent.)

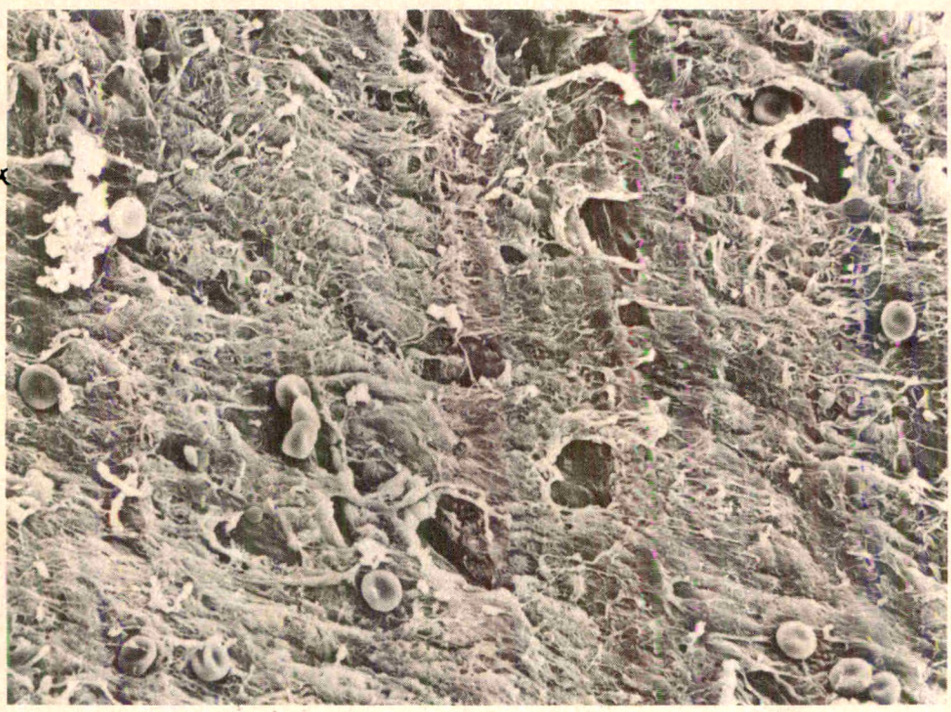

FIGURE 6. Scanning electron micrograph of the balloon injured intimal surface of the left anterior descending artery from a dog treated with dextran before angioplasty, revealing a thin layer of fibrin and a few trapped red blood cells overlying the denuded subendothelial connective tissues. No platelets are present. (×1,000 reduced by 5 percent.)

addition, the morphologic features of luminal widening induced by angioplasty was recognized. Splits of atheromatous plaques with intimal tears and some medial dissection after angioplasty were seen in the rabbit model. Similar findings were also noted in studies of hearts subjected to postmortem transluminal angioplasty.[18–20] It is therefore noteworthy that such damage (that is, dissection) did not occur in the normal coronary artery. This finding has reassuring implications for the clinical situation in which a normal coronary artery may be "dilated" by virtue of its location adjacent to a lesion undergoing angioplasty, or if, due to malpositioning of the catheter, the balloon is inflated in a segment of artery free of atherosclerosis.

The long range effects of endothelial damage induced by angioplasty remain unclear. Other than early platelet metamorphosis, we detected no changes in the endothelium and platelet carpet in the animals studied 24 hours after angioplasty. Because the subendothelium was normal rather than atherosclerotic in the model used, we cannot comment on the changes of coronary intimal surfaces after dilatation of atherosclerotic lesions. However, even without atherosclerosis, severe endothelial damage can be expected with subsequent new platelet deposition.

Platelet adhesion and endothelium: effects of pharmacologic agents: The complex relation among factors such as endothelial repair, the atherosclerotic process and platelet adhesion is poorly understood at present.[3,21,22] It is possible that the platelet adhesion rather than being deleterious may actually facilitate endothelial repair. For example, with platelet adhesion to damaged endothelium a local vasodilator and antiaggregating prostaglandin, prostacycline, is released, perhaps counteracting the release by the platelets of the potent vasoconstrictor, thromboxane A2.[22,23]

The buildup of platelet aggregates in proximal portions of atherosclerotic coronary arteries with diminished flow may lead to thrombosis, distal embolization of platelet plugs or excessive vasoconstriction with resultant ischemia.[8,15] Because platelet adhesion occurs after angioplasty, we undertook to observe the effects of various pharmacologic agents in altering this platelet adhesion to damaged endothelium. The effect of aspirin on platelet adhesion in this situation is controversial and may be dose-related.[4,12,13,15] In our model, aspirin seemed to have little effect on platelet adhesion, confirming the observation of Essien and Mustard.[13] Heparin had no visible antiplatelet effect, although fibrin deposition was greatly reduced. Low molecular weight dextran, which coats platelets and decreases platelet adhesiveness rather than affecting the enzyme systems responsible for aggregation,[24,25] caused markedly less visible platelet adhesion to damaged endothelium in the animals studied acutely. However, in the preliminary experiment with a single dog studied at 24 hours there was no effect of dextran. Confirmation of these findings awaits further study with quantative morphometric techniques of platelet adhesion. Whether dextran's acute antiplatelet effect is salutory remains to be shown by long-term observations of the endothelium after angioplasty. Nevertheless, preliminary communication of these data[26] has led to the use of dextran in most centers where percutaneous coronary

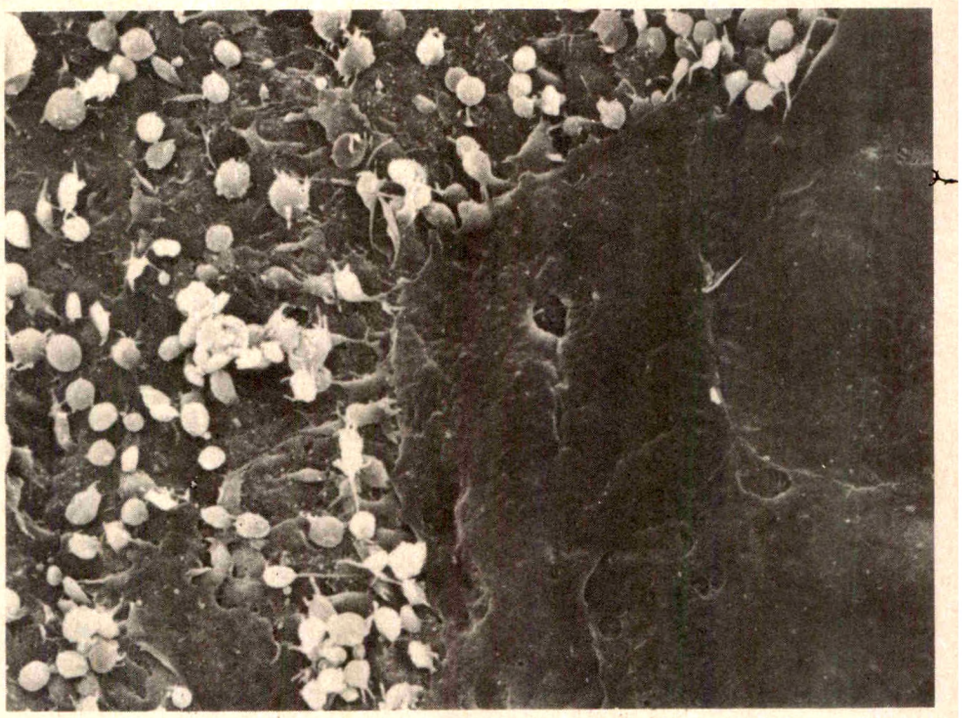

FIGURE 7. Scanning electron micrograph of left anterior descending artery from the animal treated with dextran and sacrificed 24 hours after angioplasty. Abundant platelets are evident in various stages of metamorphosis. Some adherent platelets are discoid, others have multiple pseudopodia, and many appear flattened and seem to be blending into the subendothelial tissue. Intact endothelial cells are present at right. (×2,000, reduced by 4 percent.)

transluminal angioplasty is currently being performed (Gruntzig AR, personal communication).

Implications: Transluminal angioplasty causes severe damage to in vivo normal canine coronary endothelium. Platelet adhesion after this damage may be reduced acutely with dextran. The model used in our experiments offers a method to make long-range observations helpful in understanding the possible consequences of coronary angioplasty as well the study of the effects of antiplatelet interventions. It also provides a means for further exploration of various potential forms of injury to coronary endothelium and may help clarify the role of endothelial injury and platelet deposition in atherogenesis.

NEW FOR ANGINA PECTORIS

IT HAPPENS ONLY ONCE:

E.R. SQUIBB & SONS, INC., INTRODUCES

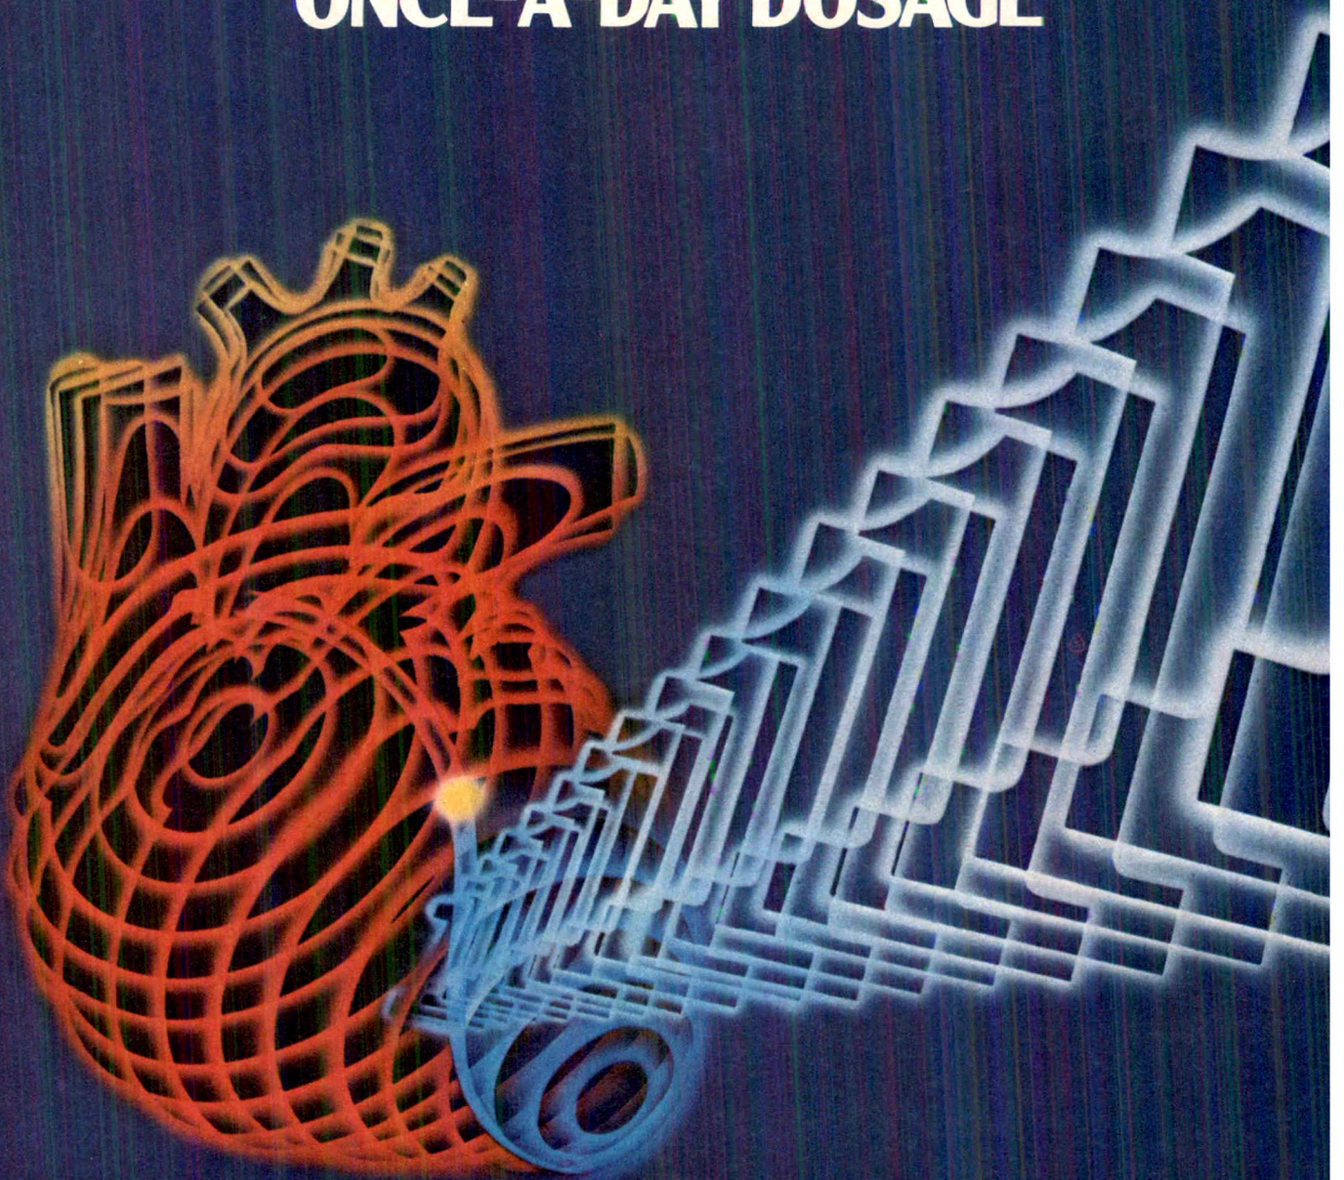
CORGARD®
nadolol tablets

SQUIBB®

See last page of this advertisement for brief summary of prescribing information.

NEW FOR ANGINA PECTORIS

CORGARD® [nadolol tablets] THE FIRST BETA-BLOCKER WITH ONCE-A-DAY DOSAGE



SQUIBB®

Corgard, once a day, decreased the frequency of anginal attacks[1]

		Mean decrease*
CORGARD, once a day	(115 patients)	**−59%**
propranolol, q.i.d.	(72 patients)	**−62%**

Corgard, once a day, in the same study, decreased nitroglycerin usage[1]

		Mean decrease*
CORGARD, once a day	(103 patients)	**−58%**
propranolol, q.i.d.	(68 patients)	**−63%**

Corgard, once a day, also in the same study, increased exercise tolerance[1]

		Mean increase*
CORGARD, once a day	(147 patients)	**+25%**
propranolol, q.i.d.	(107 patients)	**+30%**

***In the data presented above, dosages were individually titrated. Maintenance dosages for both Corgard and propranolol ranged from 40-240 mg daily. Response rates reported were after 14 weeks of therapy.**

CORGARD EFFICACY MAKES SENSE

Corgard lets the angina patient do more. Corgard, once a day, decreased the frequency of anginal attacks, improved exercise tolerance, and reduced nitroglycerin usage as effectively as propranolol given four times a day.[1]

CORGARD CARDIODYNAMIC EFFECTS MAKE SENSE

Corgard generally decreases myocardial oxygen demand. Corgard blocks catecholamine influence on myocardial work, generally decreasing oxygen demand. But unlike propranolol, Corgard has little direct myocardial depressant activity.

For a discussion of Contraindications, Precautions, Adverse Reactions, and Warnings, including avoidance of abrupt withdrawal, see brief summary of prescribing information on next page of this advertisement.

CORGARD CONVENIENCE MAKES SENSE

Corgard, once a day, offers 24-hour protection from anginal pain. Corgard offers your patient the simplest regimen available today—once-a-day dosage that can be taken without regard to meals.

THE COMMON-SENSE BETA-BLOCKER

CORGARD®
nadolol tablets

Please see brief summary of prescribing information on next page of this advertisement.

NEW ALSO FOR HYPERTENSION

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been establish

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS).
Central Nervous System — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients.
Respiratory — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients.
Miscellaneous — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, or 120 mg nadolol per tablet in bottles of 100 and 1000.

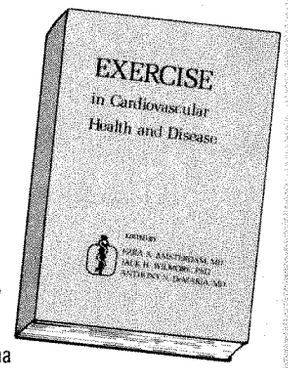
. . . for **every** professional with an interest in Exercise and the Heart

EXERCISE in Cardiovascular Health and Disease



Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS. $33.00

This comprehensive work covers every aspect of exercise and its role in **Diagnosis, Treatment,** and **Prevention** of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

"The list of contributors bespeaks its authority: outstanding physicians in cardiovascular medicine and distinguished physical educators . . . No serious student or practitioner in the field would wish to be without this remarkably thorough account . . ."
David H. Spodick, MD, St. Vincent Hospital, Worcester, Mass. in ***The Journal of the American Medical Assoc.****, June 16, 1978, Vol 239, No. 24*

"Many areas in this field which have not as yet been addressed under one cover and a few rather unique ones are mentioned . . . an important synthesis of our current knowledge in the field."
Harold T. Mankin, MD, Division of Cardiovascular Diseases and Internal Medicine, ***Mayo Clinic Proceedings****, May 1978*

Touch and Go

PDS 3036 puts you in touch with concise, meaningful data.

An alarm is displayed at the monitoring central station. You have to make a quick assessment. Is it minor? Is it serious? It's a touch and go situation you face every day. You need complete arrhythmia history, trend plots...fast. Touch a few buttons on the PDS 3036 keyboard and get the information you need at a glance, so you can react quickly.

PDS 3036 Computerized Arrhythmia Analysis System is designed for easy, fast readability...essential in touch and go situations. It organizes information for rapid interpretation.

Trend Plot includes clear display of medications and events. No footnotes. No searching the screen. Multiple trends can be displayed simultaneously, including heart rate, PVCs/minute, blood pressures and other monitored data.

Arrhythmia History is continuously updated for each patient. It includes suspected arrhythmia classifications, alarm level, time of occurrence and length of each event.

Unit Status display provides suspected arrhythmia data and heart rate for up to 16 patients. Includes patient name, bed and room number, PVCs/minute and alarm limits.

Add computerized arrhythmia analysis to your PDS 3000 or 3100 monitoring system with the compact PDS 3036. You'll have all the facts at your fingertips the next time you face a touch and go situation.

For more information contact your GE representative.

COMPUTERIZED ARRHYTHMIA ANALYSIS

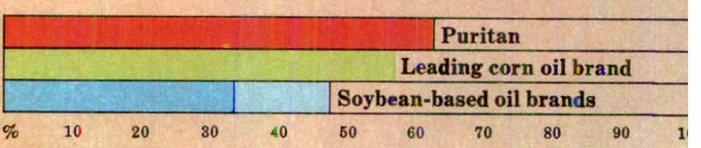
GENERAL ELECTRIC

Puritan Oil® is superior in polyunsaturates to corn oil*

A practical adjunct in serum cholesterol control

Puritan is the first major cooking oil made principally from highly polyunsaturated sunflower oil. The sunflower oil gives Puritan an edge in polyunsaturate levels over leading corn and soybean-based oils.

* **A comparison of polyunsaturate levels of major brands**



Light flavor... encourages compliance at the table

The sunflower oil also makes Puritan light tasting. In taste tests conducted with Puritan and corn oil, Puritan Oil was selected as lighter tasting by homemakers. It contributes to an appealing diet for patients and family and thus helps enhance sustained compliance with your cholesterol management program.

Clinically tested...and proven within a "real life" regimen

The nutrition department of a major university has published the results of a study[1] that evaluated a dietary serum-cholesterol-reducing program which included Puritan Oil. The study was conducted in a family situation—entire families used Puritan as part of a total serum-cholesterol-reducing diet. The data showed significant decreases in serum cholesterol levels among all participating groups. These lowered levels were reached within 10 days, and were maintained throughout the diet modification period.

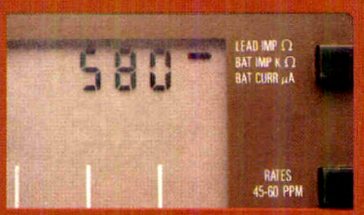
PROGRAMALITH®
IS
INTERROGATABLE

How does it work?
Why not ask it yourself!

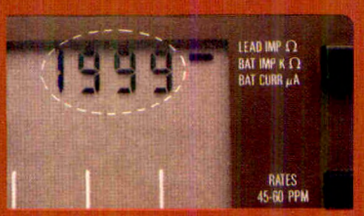
Pacesetter® Systems, Inc.

PROGRAMALITH®
IS
DIAGNOSTIC

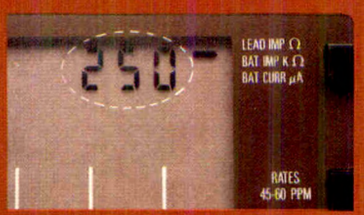
LEAD IMPEDANCE



Non-invasive measurement of lead impedance can be used to monitor changes with time.

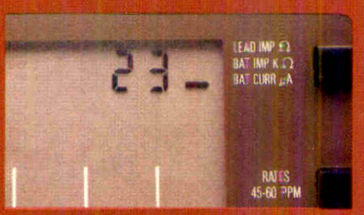


Shows fractured or improperly connected leads.

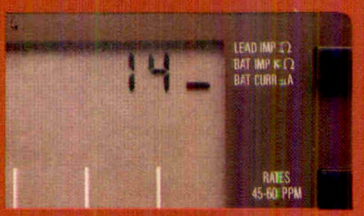


Shows shorted leads, insulation faults or low impedance lead systems.

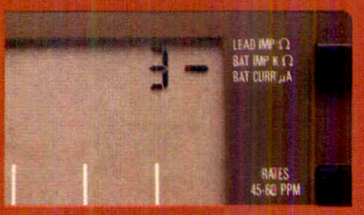
BATTERY CURRENT



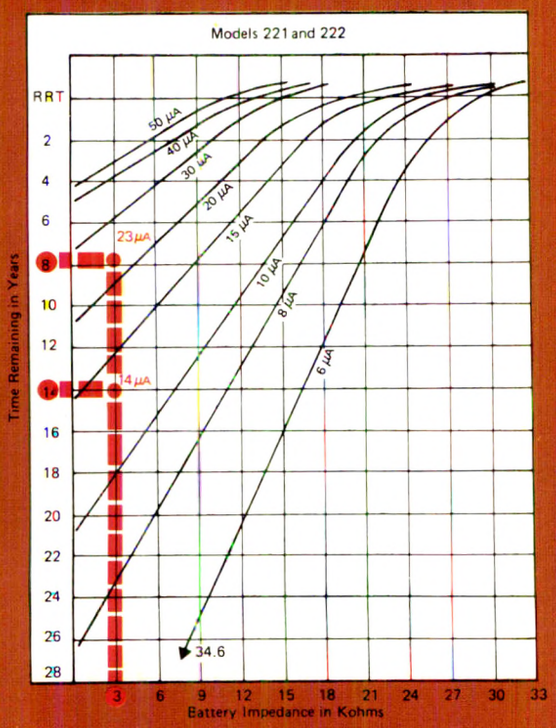
Battery current (80 PPM, 0.8 ms pulse width and 5.0 volt output pulse).



Battery current (same parameters but programmed to 2.5 volt output pulse) adjusted to optimal efficiency



In addition to rate decrease and pulse width increase, a third RRT indicator is provided. RRT is approximately 21 kilohms at standard settings. Remaining service life is simply determined.



OPTIMIZING THE SYSTEM

With Programalith you can determine all parameters affecting pacemaker performance and optimize the system to best satisfy the patient's needs while extending service life.

Collateral Vessels Between the Coronary and Bronchial Arteries in Patients With Cyanotic Congenital Heart Disease

HARRAN Y. ZUREIKAT, MD, FACC

Amman, Jordan

Selective coronary arteriography (using the Sones technique) was performed in 67 patients with congenital heart disease aged 1 to 33 years. Five of the 23 patients with cyanotic congenital heart disease had collateral vessels between the coronary and bronchial arteries; none of the 44 patients with noncyanotic congenital heart disease had such vessels. Each of the five patients with collateral vessels had severe obstruction of the right ventricular outflow tract or the pulmonary valve plus a ventricular septal defect and a right to left shunt. It appears that such collateral vessels from the coronary arteries provide an increment to pulmonary blood flow in patients with cyanotic congenital heart disease and diminished pulmonary flow.

The presence of precapillary anastomoses between the coronary arteries and extracardiac vessels was first described by Von Haller[1] in 1803. Hudson et al.[2] in 1932 injected the coronary arteries with India ink and demonstrated anastomoses between the coronary arteries and the vasa vasorum of the thoracic aorta and pulmonary arteries as well as vessels of the parietal pericardium, diaphragm, pleural surfaces of the lung, bronchi, mediastinum, trachea and esophagus. Voss[3] in 1856 in a postmortem study of a man with pulmonary atresia demonstrated anastomoses between the coronary arteries and the bronchial arteries. Modern investigators have identified collateral flow from the coronary arteries to the bronchial arteries with angiography in patients with chronic obstructive lung disease[4,5] and from the bronchial to the coronary arteries in patients with coronary artery disease.[6–8] Bjork[9] demonstrated angiographically anastomoses between the coronary and bronchial arteries in patients with tetralogy of Fallot and pulmonary atresia. The purpose of this paper is to report the results of a prospective study of the frequency of coronary-bronchial arterial collateral vessels in patients with cyanotic and acyanotic congenital heart disease.

Methods

Patients: Between November 1975 and January 1978 selective coronary arteriography was performed in 67 of 181 patients with congenital heart disease undergoing right and left heart catheterization at King Hussein Medical Center. Arteriography was performed in all patients whose general condition was good at the end of the catheterization study. Of 67 patients, 23 had cyanotic congenital heart disease; their ages ranged from 1 to 33 years (mean 12). Among these 23 patients 18 had tetralogy of Fallot; 1 had levotransposition, ventricular septal defect and severe pulmonary stenosis; and 4 had double outlet right ventricle with pulmonary stenosis. None of the 67 patients had undergone cardiac surgery.

Catheterization procedures: Right and left heart catheterization was performed by way of an antecubital vein and the brachial artery in older children and through the long saphenous vein and the femoral artery in smaller children. Selective coronary arteriography was performed with the Sones technique.[10]

From the Department of Cardiology, King Hussein Medical Center, Amman, Jordan. Manuscript received July 25, 1979; revised manuscript received and accepted October 17, 1979.

Address for reprints: Harran Y. Zureikat, MD, Department of Cardiology, King Hussein Medical Center, Amman, Jordan.

TABLE I

Age, Diagnosis and Origin of Collateral Vessels in Five Patients

Case	Age (yr)	Diagnosis at Cardiac Catheterization	Collateral Vessels to Bronchial Arteries From Atrial Branches of:
1	33	Tetralogy of Fallot	LMCA, LCx, RCA
2	12	Tetralogy of Fallot	LCx, RCA
3	12	Tetralogy of Fallot	RCA
4	9	DORV	LCx, RCA
5	13	Tetralogy of Fallot	LMCA

DORV = double outlet right ventricle; LCx = circumflex branch of the left coronary artery; LMCA = left main coronary artery; RCA = right coronary artery.

Routinely one injection was made in the right coronary artery in a steep left anterior oblique projection and two injections were made in the left coronary artery in steep left anterior oblique and shallow right anterior oblique projections. Further injections were made whenever cinefluorography revealed an abnormality. The contrast material used was Urografin 76 percent® (Schering AG Berlin) and the maximal dose was 2.5 ml/kg body weight in cyanotic patients and 3.5 ml/kg in acyanotic patients.

Results

Of the 23 patients with cyanotic congenital heart disease 5 had angiographically demonstrable coronary-bronchial arterial collateral vessels (Table I). In

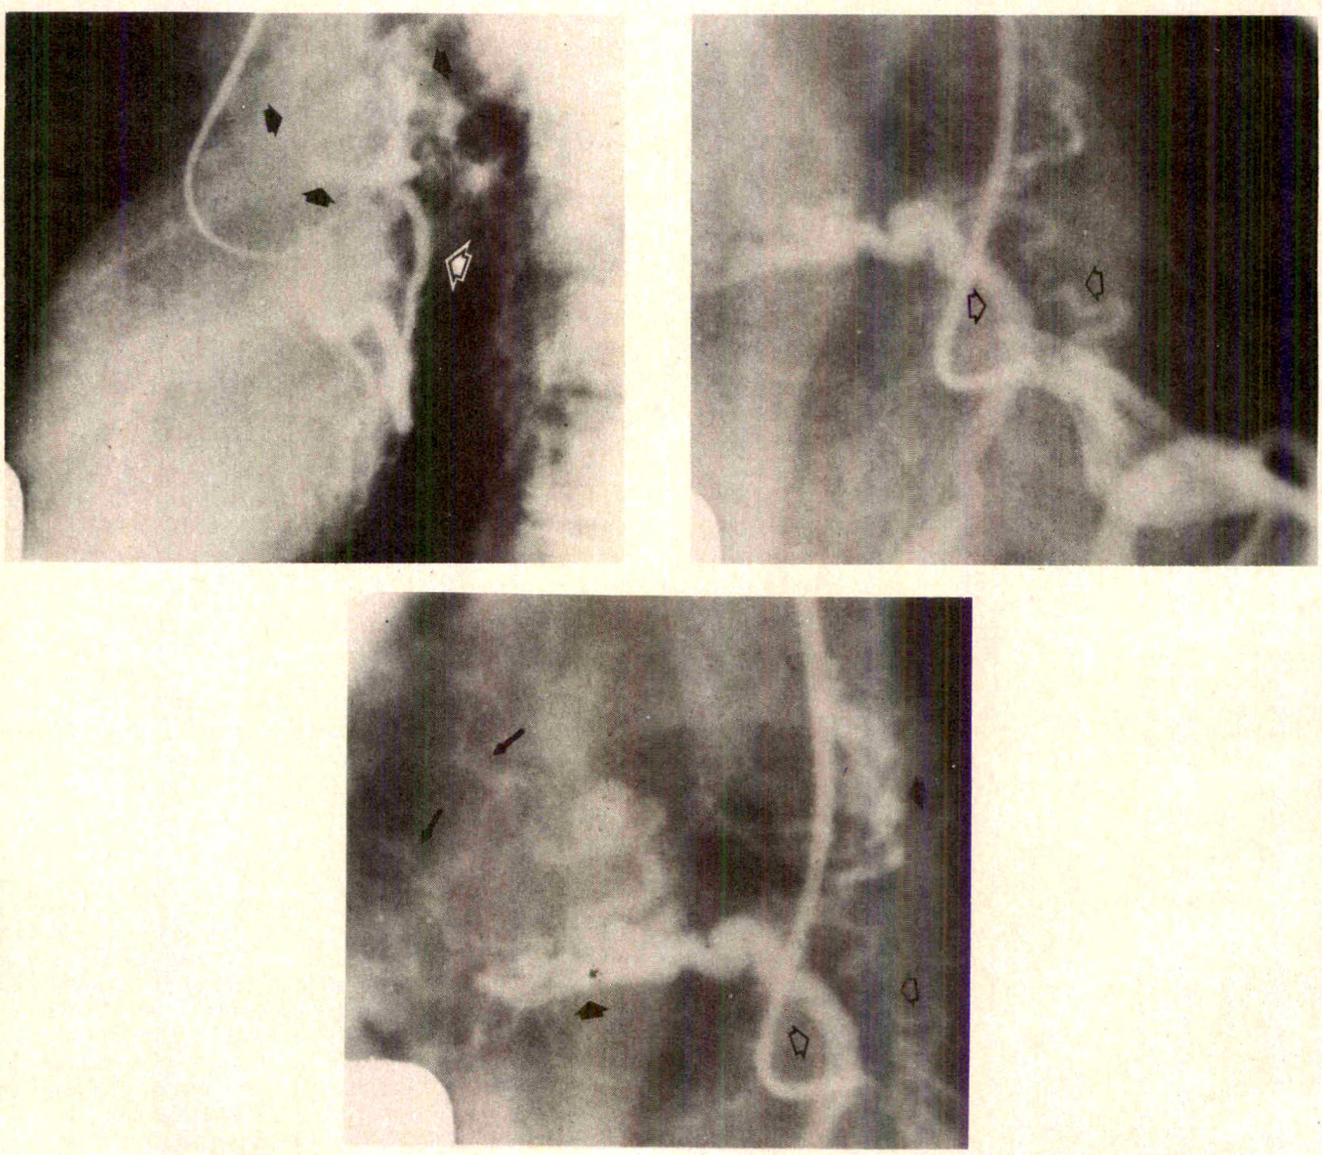

FIGURE 1. Patient 1. Tetralogy of Fallot. **Left coronary angiograms. Upper left,** in left anterior oblique projection showing collateral vessels to the bronchial arteries around a main bronchus (**black arrows**) from a large atrial branch of the circumflex artery (**white arrow**). **Upper right,** in right anterior oblique projection, early filling phase, showing collateral vessels to the bronchial arteries from two atrial branches arising from the circumflex artery and the left main trunk (**arrows**). **Bottom,** in right anterior oblique projection, late filling phase, showing several tortuous bronchial arteries (**short black arrows**) communicating with segmental pulmonary arteries (**long black arrows**).

each case these vessels arose from the atrial branches of either the right coronary artery, the left main trunk, the circumflex branch of the left coronary artery or combinations of these (Table I). These collateral channels communicated with multiple segmental bronchial arteries; the method of collateral communication varied from three or four large branches (Fig. 1) to a myriad of small vessels (Fig. 2).

Comparison of the size of the anastomotic vessels with the size of the catheter indicated that the blood flow through these vessels moderate to large, although the actual flow could not be calculated. In one case (Patient 5) the communications were of small size. Direct communications between the coronary arteries and the main pulmonary arteries or their major branches were not seen in any patient. In Patient 1, whose collateral channels were very large, it was possible to trace the contrast material from the coronary to the bronchial arteries and then to the tertiary branches of the pulmonary arteries. Cine films revealed that the anasto-

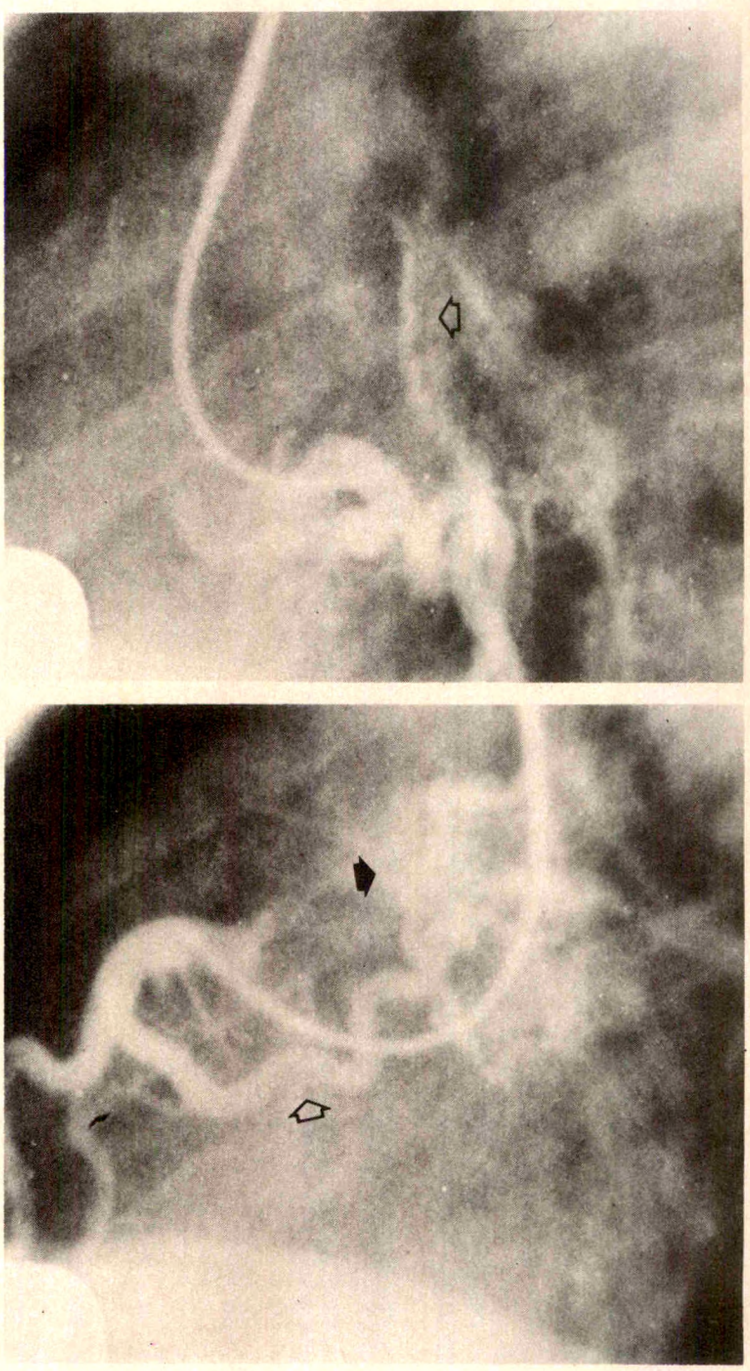

FIGURE 2. Patient 4. Double outlet right ventricle with malposition of the great vessels. **Top,** left coronary arteriogram in left anterior oblique projection showing a small atrial branch of the circumflex artery (**arrow**) providing collateral vessels to segmental bronchial arteries in the hilar region. **Bottom,** right coronary arteriogram in left anterior oblique projection showing a large atrial branch (**blank arrow**) communicating with a myriad of small branches of a bronchial artery (**black arrow**).

moses between the bronchial arteries and the segmental pulmonary arteries occurred at a precapillary level.

Coronary-bronchial collateral vessels were not seen in any of the 44 patients with acyanotic congenital heart disease, including 6 patients with severe pulmonary stenosis. There were no patients studied with cyanosis and high pulmonary flow.

The presence of collateral vessels could not be suspected clinically; no patient had auscultatory bruits or characteristic X-ray findings or electrocardiographic evidence of ischemia.

Discussion

Incidence of coronary-bronchial collateral channels: In patients with cyanotic congenital heart disease and severe reduction in pulmonary flow, alternate pathways may develop to achieve greater pulmonary blood flow. Although it has long been known that such patients have extensive communications between the bronchial and pulmonary arteries, little attention has been paid to the development of collateral flow to the lungs from the coronary arteries. Selective coronary arterial injection is seldom performed when studying cyanotic patients, and these collateral vessels cannot usually be demonstrated by aortic root angiograms. With the exception of the report of Bjork,[9] who demonstrated coronary-bronchial collateral channels in 6 of 7 patients with pulmonary arterial atresia and in 5 of 60 patients with tetralogy of Fallot on right ventricular and aortic root angiograms, such collateral vessels have not been described in other large series.[11,12] In each of the five patients in our study the collateral channels were not visualized in aortic root angiograms.

The presence of coronary-bronchial collateral vessels is not limited to patients with cyanotic congenital heart disease. Moberg[8] demonstrated their presence at postmortem study in all specimens studied (69 adults and 7 newborn infants). In all specimens the communications were present between the bronchial arteries and the atrial branches of the coronary arteries. It appears that these collateral channels have little functional significance but they could widen and become functional when a significant pressure gradient exists between the coronary and bronchial circulations. Hence, they are occasionally demonstrated in patients with coronary artery disease[6–8] and chronic obstructive lung disease.[4,5]

In our series coronary-bronchial collateral vessels were demonstrated only in patients with diminished pulmonary blood flow and were not seen in any of the 44 acyanotic patients with normal or increased pulmonary blood flow. The presence of collateral vessels and their size were not related to the arterial oxygen saturation. In Patient 1 coronary arteriography repeated 14 months after successful total correction revealed that the coronary-bronchial collateral vessels were still present although much smaller in size.

Bronchial steal: Bjork[9] suggested that the coronary to bronchial arterial flow in patients with cyanotic congenital heart disease might deprive the myocardium of a fair amount of its blood supply, producing a bronchial arterial steal syndrome; similarly, other investigators[4,5] reported angina-like chest pain in patients who had normal coronary arteries and coronary bronchial arterial anastomoses. Although the collateral flow was thought to be significant in four of five patients in our study, no patient had chest pain or ischemic changes in the electrocardiogram. Patients with cyanotic congenital heart disease tend to have large coronary arteries as a result of ventricular hypertrophy and myocardial tissue hypoxia, and it is also possible that the presence of coronary-bronchial communications in these patients is yet another stimulus for augmenting coronary blood flow.

Hypoxemic episodes: In patients with tetralogy of Fallot hypoxemic episodes may result in part from a sudden increase in resistance in the outflow tract of the right ventricle.[13] Look and Bates[14] using a hemodynamic model developed for tetralogy of Fallot stressed the importance of the extent of aortopulmonary collateral flow as a key compensatory response in determining the severity and incidence of the hypoxemic episodes. In other words, patients with a relatively severe infundibular stenosis and small aortopulmonary flow through collateral channels may be susceptible to hypoxemic episodes whereas patients with a large collateral flow may not.

In our series none of the 4 patients with tetralogy of Fallot and coronary-bronchial collateral channels had hypoxemic episodes, compared with 5 of the remaining 14 patients with tetralogy and no coronary-bronchial collateral channels. The two groups were comparable in degree of cyanosis; the mean arterial oxygen saturation was 77 percent for the group with collateral channels and 75.5 percent for those without them. Although the number of patients is too small to draw any definite conclusions it may be that coronary-bronchial collateral vessels provide an increment to pulmonary blood flow or that the presence of these vessels is a manifestation of extensive aortopulmonary collateral channels in such cases.

Thirty patients with a double chamber right ventricle were seen during a 7 year period. The majority of patients had associated cardiac anomalies, most commonly a ventricular septal defect. In this series, as in others, the history, clinical examination, chest roentgenogram and echocardiogram were inconclusive for diagnosing double chamber right ventricle. Symptoms were generally related to the severity of the associated anomalies.

In 40 percent of the patients reviewed, upright T waves were found in lead V_3R as the only electrocardiographic finding suggestive of right ventricular hypertrophy. Because upright T waves in lead V_3R in the *absence* of other evidence of right ventricular hypertrophy are not commonly seen in patients with an isolated ventricular septal defect or a defect associated with other forms of right ventricular outflow obstruction, this finding should alert the cardiologist to the possibility of the presence of double chamber right ventricle prior to cardiac catheterization.

An anomalous muscle bundle obstructing the sinus portion of the right ventricle was first described by Keith[1] in 1909, but has received significant attention only since the advent of open heart surgery. The presence of an anomalous muscle bundle may produce a pressure gradient between the proximal inflow area and the distal subinfundibular and outflow areas of the right ventricle, thus resulting in double chamber right ventricle.[2–11] Although the anomalous muscle bundle is relatively rare as an isolated congenital cardiac anomaly, its association with other significant cardiac anomalies, usually ventricular septal defect, has made its recognition increasingly important.[2–5] From previous reports,[2–4] however, it is apparent that there are no specific symptoms or clinical findings that suggest the diagnosis of double chamber right ventricle, either isolated or associated with a ventricular septal defect. Furthermore, the electrocardiogram and chest roentgenogram are frequently normal or show changes that may not be helpful in differentiating this anomaly from other congenital heart defects with or without an anomalous muscle bundle.[2–4] Thus, although the diagnosis may be suspected after meticulous attention to the sum of clinical information, it is often missed and the correct diagnosis is usually made from angiocardiographic studies performed during cardiac catheterization. A clinical or noninvasive diagnostic clue that would alert the cardiologist to the possible presence of double chamber right ventricle would therefore be of significant value.

On review of patients diagnosed as having double chamber right ventricle at Children's Hospital of Pittsburgh, examination of the electrocardiograms revealed a significant number with upright T waves in the right precordial leads, with no other electrocardiographic findings of right ventricular hypertrophy. A further investigation of this association serves as a basis for this report.

Methods

Patients: During the period from 1969 to 1976, a total of 30 patients with a diagnosis of double chamber right ventricle were seen at this hospital. In each case the diagnosis was confirmed by cardiac catheterization and cineangiocardiography. All inpatient and outpatient records, electrocardiograms, vectorcardiograms, echocardiograms, cardiac catheterization data, findings at intracardiac repair and autopsy protocols were reviewed and tabulated. Only patients with double chamber right ventricle with or without ventricular septal defect were included in the study, whereas patients with transposition of the great arteries or atrioventricular or semilunar valve atresias were not considered.

Electrocardiographic criteria: The electrocardiographic diagnosis of right ventricular hypertrophy was made according to the following standard criteria currently used in our institution[12–15]: (1) An RsR′ pattern in the right chest leads (V_3R, V_1) with a narrow QRS complex and an R′ wave greater than 10 mm in height. (2) A tall (greater than 10 mm) R wave in the right chest leads (V_3R, V_1) with the R wave greater than 75 percent of the R + S waves in infants and greater than 50 percent of the R + S waves in children. (3) A qR pattern in lead V_3R or V_1 at any age. (4) A positive T wave in lead V_3R or V_1 in children between 1 week and 10 years of age. Right axis deviation and a dominant R wave in lead aVR were considered suggestive but not diagnostic of right ventricular hypertrophy without the foregoing evidence of hypertrophy in the precordial leads.

Results

Clinical features: Of the 30 patients with a diagnosis of double chamber right ventricle who were seen during the 7 year period, 18 were male and 12 female. No significant prenatal history was noted in these patients. Four patients (13 percent) had additional noncardiac congenital anomalies. A plateau, pansystolic cardiac murmur was first heard soon after birth in 12 patients and before the age of 1 year in 14 others. Eleven patients were first referred to the cardiologist before age 6 months, four before age 1 year, six between 1 and 2 years and nine at a later age. Mild congestive heart failure was present in six patients (20 percent) and was the reason for referral in each; five of these patients were seen before age 1 year. Fifteen patients were initially diagnosed clinically as having ventricular septal defect and associated pulmonary stenosis, 9 as having ventricular septal defect alone, 3 pulmonary stenosis alone, and 3 other cardiac anomalies.

* Positive T wave in V_3R and V_1 present since before the patient was 8 years of age.
N = normal; RVH = right ventricular hypertrophy; T = T wave criteria; V = voltage criteria; ± = biphasic T wave.

Electrocardiographic findings: The patients' ages, electrocardiographic findings and right to left ventricular pressure ratios at cardiac catheterization are listed in Table I and the electrocardiographic findings and precatheterization clinical diagnoses in Table II. Of the 30 patients, 12 (40 percent) had upright T waves in lead V_3R as the only electrocardiographic finding suggestive of right ventricular hypertrophy (Fig. 1). Right ventricular hypertrophy was evidenced by voltage criteria alone in 11 patients and by both voltage criteria and T wave changes in 3 patients. Four patients were considered normal.

Echocardiography was performed in only seven patients and was not found to be helpful in the diagnosis of double chamber right ventricle.

Vectorcardiography was performed in 10 patients. In six with electrocardiographic evidence of right ventricular hypertrophy, a horizontal plane QRS loop characteristic of right ventricular hypertrophy confirmed the electrocardiographic findings. In 4 of the 12 patients who had upright T waves in the right precordial leads as the only electrocardiographic abnormality, vectorcardiography demonstrated the findings shown in Figure 1. More than 50 percent of the horizontal plane vector QRS loop was oriented anterior to the E point, with the remainder of the QRS loop oriented posteriorly and to the right. These vectorcardiographic findings suggest right ventricular hypertrophy.

Cardiac catherization findings: All patients underwent one cardiac catheterization and eight had a second catheterization study. Seven patients underwent cardiac catheterization before age 1 year, 14 between 1 and 6 years and 9 at a later age. Of the eight patients who had a second cardiac catheterization, six showed an increase in right ventricular pressure greater than 20 mm Hg at the second catheterization, whereas two had the same right ventricular pressure. Despite this hemodynamic change, none of these eight patients had a change in the electrocardiographic findings.

Of the 30 patients, 4 had isolated double chamber right ventricle (without ventricular septal defect), whereas 26 (87 percent) were diagnosed as having both a ventricular septal defect and double chamber right ventricle. Seventeen of the latter 26 patients had additional cardiac findings: patent foramen ovale (11 patients); atrial septal defect and aneurysm of the membraneous interventricular septum (1); aneurysm of the membraneous septum alone (2); pulmonary valve stenosis (2) and patent ductus arteriosus (1). Two of the four patients with isolated double chamber right ventricle had associated valvular pulmonary stenosis. One of these two and one of the others without pulmonary

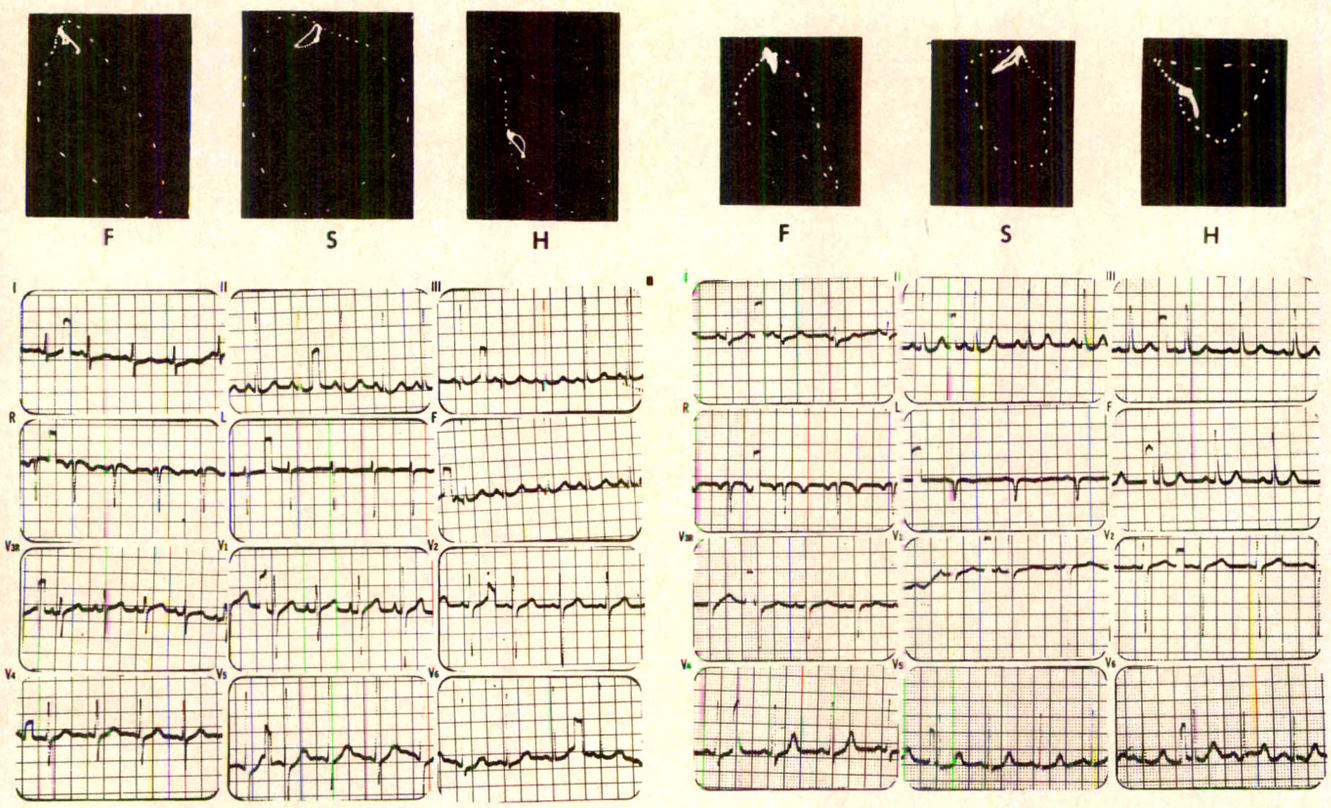

FIGURE 1. Electrocardiograms and vectorcardiograms in two patients aged, respectively, 6 years (**left**) and 4 years (**right**) with double chamber right ventricle. Note the upright T wave in lead V_3R without other electrocardiographic evidence of right ventricular hypertrophy. The horizontal (H) plane of the vectorcardiogram suggests right ventricular hypertrophy. F = frontal plane; S = sagittal plane.

stenosis had an aneurysm of the membraneous interventricular septum and probably previously had a ventricular septal defect that had subsequently closed spontaneously. The remaining patient had associated tricuspid regurgitation.

Correlation of right ventricular pressure and electrocardiograms: Table III summarizes the electrocardiographic findings in relation to the ratio of right and left ventricular pressures found during cardiac catheterization. Eighteen patients had a right ventricular systolic pressure that was at least 75 percent of left ventricular systolic pressure. In 13 of the 18 pressure in the right ventricle was equal to systemic pressure, in 2 it was greater than systemic pressure, and in 3 it was 78, 85 and 87 percent of systemic pressure, respectively. Of these 18 patients with right to left ventricular pressure ratio of 75 percent or greater, 6 had upright T waves in lead V_3R as the only indication of right ventricular hypertrophy and 1 had an electrocardiogram that was considered within normal limits.

Discussion

Clinical features: The presence of a double chamber right ventricle as a result of obstruction by an anomalous muscle bundle poses a difficult diagnostic problem because the clinical findings often mimic those of other congenital cardiac anomalies. Double chamber right ventricle is rarely seen as an isolated congenital heart defect. It is most commonly associated with ventricular septal defect (an incidence of up to 80 to 90 percent in different series[2–4,6]) and more rarely with pulmonary valve stenosis alone.[7–9] All of our 30 patients had associated cardiac abnormalities, 87 percent having a ventricular septal defect.

The neonatal history is usually normal[2] and none of our patients had neonatal symptoms that might be associated with this cardiac anomaly. Four (13 percent) of the 30 patients had noncardiac congenital anomalies with no specific syndrome evident.

There was no correlation between the clinical features, electrocardiograms or hemodynamic findings in these patients. The clinical symptoms found in these patients are mainly dependent on the severity of the associated cardiac anomalies. These can range from none at all to those of congestive heart failure.[6] Of the 30 patients, only 6 (20 percent) had cardiac symptoms when first referred for evaluation and, of these, only 2 (7 percent) had symptoms severe enough to warrant hospitalization. Thus, 24 (80 percent) of our 30 patients were asymptomatic and were evaluated only because of a heart murmur.

Electrocardiographic features: The reported electrocardiographic findings considered typical of double chamber right ventricle include an inconspicuous R wave in lead aVR and prominent R wave with little or no S wave in lead V_4R, with normal voltage in lead V_1 and the remaining precordial leads.[2,6,8,9] These electrocardiographic findings have been attributed to absence of hypertrophy of the distal right ventricular chamber.[2–5,7,8] However, in other studies these changes have been found in a relatively small number of patients with double chamber right ventricle, and many patients exhibit normal electrocardiographic patterns on repeated evaluation.[4] In our series of 30 patients, 4 (13 percent) had normal electrocardiograms. In two of these patients right ventricular pressure was less than 50 percent of systemic pressure, in one it was 67 percent of systemic pressure and in one it was at systemic level. Thus, a normal electrocardiogram in this group did not preclude the presence of significant proximal right ventricular hypertension.

Upright T waves in lead V_3R were found in 15 patients. In 12 patients this was the only electrocardiographic finding indicative of right ventricular hypertrophy, although pressure in the proximal right ventricular chamber in most of these patients ranged from 50 percent of systemic pressure to suprasystemic levels. Vectorcardiography was performed in only 4 of these 12 patients, but the findings suggested right ventricular hypertrophy. No definite statements can be made for the group as a whole on the basis of these four studies alone. However, the majority of the horizontal plane forces on these vectorcardiograms were oriented perpendicularly to both the right and left precordial electrocardiogram leads; thus, the absence of large QRS deflections in these leads resulted in an apparently normal electrocardiogram by voltage criteria.

There was no distinct relation in this series between the patients' age, electrocardiographic findings and the degree of proximal right ventricular hypertension. Al-

TABLE II

Electrocardiographic Findings and Precatheterization Clinical Diagnosis

	Electrocardiographic Findings				
	Right Ventricular Hypertrophy				
Clinical Diagnosis	Voltage Only	Voltage + T Wave	T Wave Only	Normal	Total
VSD alone	6	1	4	3	14
VSD + PS	5	1	7	—	13
PS alone	—	1	1	1	3
Total	11	3	12	4	30

PS = pulmonary stenosis; VSD = ventricular septal defect.

TABLE III

Electrocardiographic Findings And Right Ventricular Pressure Data

	Electrocardiographic Findings				
RV/LV	Right Ventricular Hypertrophy				
Pressure Ratio	Voltage Only	Voltage + T Wave	T Wave Only	Normal	Total
< 50%	1	—	3	2	6
50–75%	2	—	3	1	6
> 75%	8	3	6	1	18
Total	11	3	12	4	30

RV/LV pressure ratio = ratio between peak systolic pressure in the right (RV) and left ventricles (LV).

though an upright T wave in lead V_3R was found more frequently in patients aged 2 years or more (14 of 21 patients) than in those less than 2 years of age (1 of 9 patients), the elevation of right to left ventricular pressure ratio was randomly distributed among these groups (Tables I and III).

Comparison with other congenital heart lesions: Upright T waves in the right precordial leads have been reported in infants with tetralogy of Fallot before the development of cyanosis and in children with other forms of right ventricular outflow tract obstruction with moderate to severe right ventricular hypertension.[12–15] These T wave changes usually occur in conjunction with findings of moderate to severe right ventricular hypertrophy by voltage criteria. However, upright right precordial lead T waves in the *absence* of other electrocardiographic evidence of right ventricular hypertrophy, as seen in our patients with double chamber right ventricle, have not been reported in children with ventricular septal defect alone or combined with other types of right ventricular outflow obstruction. Although an upright T wave in lead V_1 with an otherwise normal electrocardiogram has been reported in children with mild pulmonary valve stenosis,[16] in our experience this is a rare phenomenon. In addition, the clinical findings of mild pulmonary valve stenosis would not resemble those of patients with double chamber right ventricle.

In patients with moderate to severe right ventricular hypertension, the electrocardiogram and vectorcardiogram usually exhibit characteristic voltage abnormalities that suggest right ventricular hypertrophy. These changes are often accompanied by a more anteriorly oriented T wave vector and an upright T wave in electrocardiographic leads V_3R and V_1. In patients with double chamber right ventricle, as compared with those with other forms of right ventricular outflow tract obstruction, the high pressure proximal chamber is reduced in size by the anomalous subinfundibular muscle bundles. It is possible that this reduction in size of the proximal chamber results in the anterior shift of the T vector with much less of a shift of the QRS vector, thus producing the electrocardiographic and vectorcardiographic features observed in many of the patients in our series.

This study suggests that the cardiologist should be alerted to the possibility of double chamber right ventricle by the appearance of upright T waves in lead V_3R *without* other evidence of right ventricular hypertrophy in patients with the clinical diagnosis of ventricular septal defect alone or in association with other anomalies.

Saralasin Infusion in Screening Patients for Renovascular Hypertension

LAWRENCE R. KRAKOFF, MD, FACC
ARTUR B. RIBEIRO, MD
JANET U. GORKIN, MD
KATHERINE R. FELTON, MS

New York, New York

The usefulness of screening patients for renovascular hypertension by infusion of saralasin, a competitive antagonist of angiotensin II, was evaluated. Responses were compared in 19 patients with proved renovascular hypertension and in 34 without renovascular hypertension, as indicated by renal arteriography and renal venous renin studies. Saralasin infusion was carried out in the morning after furosemide, 80 mg by mouth, had been given the previous evening. Seventy-five percent of patients with and 12 percent of those without renovascular hypertension had a reduction in diastolic pressure of 5 mm Hg or more during saralasin infusion; only 45 percent of patients with and 6 percent of those without renovascular hypertension had a reduction of 10 mm Hg or greater during infusion. In comparison, 80 percent of patients with and 18 percent of those without renovascular hypertension had a positive intravenous pyelogram. The predictive value of a positive saralasin test (5 mm Hg or greater reduction in diastolic pressure) was calculated for varying prevalence rates of renovascular hypertension with use of Bayes theorem. The results indicate that when the prevalence rate of renovascular hypertension among hypertensive patients is 5 percent, only 25 percent of positive saralasin tests will correctly predict its presence.

Renovascular hypertension is the most common form of surgically curable hypertension. Estimates of its prevalence have varied depending on whether the patients studied were seen in an outpatient clinic or in a specialty care center.[1] Until recently, screening of hypertensive patients for renovascular hypertension has relied upon use of the rapid sequence intravenous pyelogram or radioisotope renogram. Both techniques have been extensively studied for their value in this context.[2] Recent emphasis has been placed on the renin-angiotensin system in screening for renovascular hypertension. Many patients with proved renovascular hypertension have high levels of plasma renin activity or have striking reductions in blood pressure when treated with propranolol, the renin-lowering beta receptor blocking drug.[3] Specific blockade of the renin-angiotensin system with administration of peptide analogs of angiotensin II such as saralasin[4–9] or by inhibition of converting enzyme[10] has also caused large reductions in pressure in patients with renovascular hypertension.

It has been suggested that saralasin might have usefulness as a screening test. We present observations of this angiotensin antagonist in screening 53 patients for renovascular hypertension, 19 patients with and 34 patients without this condition as assessed from intravenous pyelograms and renal arteriography.

Methods

Selection of patients: Patients were referred by their physician because renovascular hypertension was suspected or was to be excluded by renal arteriography. The usual reasons for referral were (1) abnormal intravenous pyelo-

gram, (2) recent onset of hypertension in a young adult, (3) "resistance" to antihypertensive drug treatment, and occasionally (4) presence of an abdominal bruit.

Protocol: Administration of all antihypertensive drugs was discontinued 1 week before the patients' admission, but a diet without added salt was prescribed. Most studies were performed after patients were hospitalized on the medical services of The Mount Sinai Hospital or the Clinical Research Center. Two studies were performed in outpatients who adhered rigidly to the conditions of the protocol. On the 1st day of study, a complete history and physical examination were performed. SMA 6 and 12 channel blood chemistry determinations were obtained as were a spot urine test for metanephrine (if pheochromocytoma had not been previously excluded) and a pregnancy test for women of child-bearing potential. Patients were kept on a no added salt diet (80 to 100 mEq sodium). A complete 24 hour urine collection for electrolyte determinations was obtained on the 2nd day as was a venous blood sample for plasma renin activity at midday after the patient had been out of bed for 3 hours.

The saralasin infusion study was performed on the morning of the 3rd or 4th day after a diuresis had been produced by administration of furosemide, 80 mg orally at 7 p.m. the preceding evening. All infusions were carried out in a special study area with a quiet atmosphere. A slow intravenous infusion of 5 percent dextrose in water was initiated and maintained throughout the study. Blood pressure was monitored at 2 minute intervals with the Arteriosonde 1216 (Roche Instruments, Inc.). All patients were studied in the supine position. After a 60 minute observation period, a venous blood sample for plasma renin activity was obtained. Blood pressure was monitored for an additional 30 minutes. Then 18 mg of saralasin was infused over 30 minutes utilizing a Harvard syringe pump. At the end of the infusion a second venous blood sample for measurement of plasma renin activity was obtained. Blood pressure was monitored for an additional 60 minutes after termination of the saralasin infusion.

Responses to saralasin infusion were assessed by using the *t* test for unpaired variates to compare the average of 10 blood pressure measurements preceding infusion with the last 10 measurements before cessation of the infusion. Thus, the transient pressor action that may occur during the first 5 minutes of infusion[11] was avoided in the analysis. This method avoids biased interpretation and adjusts for variability of arterial pressure as revealed in either the preinfusion control period or during infusion of the peptide. The data were easily processed through programs written for the Tektronix-31 desk top computer.

Bilateral renal venous catheterization for plasma renin activity and renal arteriography were performed on the 5th or 6th day. Lateralization of renin production was assessed by the criteria of Vaughan et al.[12]

Renovascular hypertension was considered present on the basis of (1) significant anatomic lesions of main renal arteries or branches, (2) response to surgery, and (3) lateralization of renin production in cases of unilateral renal arterial stenosis. Plasma renin activity was determined by radioimmunoassay of generated angiotensin I according to methods employed in this laboratory.[13,14] This research protocol was approved by The Mount Sinai Hospital Committee for Human Research. Informed consent was obtained in advance from all subjects studied.

Results

Clinical features of patients: The characteristics of the patients with and without renovascular hypertension are summarized in Table I. The wide age range in the group with renovascular hypertension reflects the presence of younger patients with fibromuscular dysplasia and older patients with atherosclerotic renal artery disease. Although the mean age of the two groups was not significantly different, that of 35 years for the group without renovascular disease indicates that younger hypertensive patients were referred for evaluation. The ratio of women to men was nearly 2:1 in the group with renovascular hypertension; this ratio was of borderline statistical significance when compared with the sex ratio of the group without renovascular hypertension. The ratio of white to black patients was similar in both groups.

Intravenous pyelography: The results of this procedure in both groups of patients are shown in Table II. A predominance of positive intravenous pyelograms was apparent in the group with renovascular hypertension. Of the six patients with an abnormal intravenous pyelogram in the group without renovascular hypertension, one had hydronephrosis, one had multiple cysts and four had hypoplastic kidneys as subsequently revealed by renal arteriography. None of these patients had lateralization of renal venous renin activity. Four patients with renovascular hypertension had a normal intravenous pyelogram. One of these had bilateral renal arterial stenosis and one had branch renal arterial obstruction. The others had significant anatomic stenosis of the main renal artery.

Plasma renin activity: Measurements of plasma renin activity determined at midday on day 2 of the study are shown in Table III. Also given is the 24 hour excretion rate of sodium for the same day and the plasma renin activity determinations immediately before and at the end of the saralasin infusion. Midday measurements were significantly higher in the group with renovascular hypertension. For both groups there

was excellent correlation between the midday and preinfusion plasma renin activity levels ($r = 0.68$, $p < 0.001$), the latter having been obtained in the supine position, but on the morning after furosemide given on the preceding evening. After saralasin infusion plasma renin activity increased significantly in the group with renovascular hypertension, but did not change significantly in the group without renovascular hypertension. The resultant postinfusion plasma renin activity levels were nearly fourfold greater in the group with than in the group without renovascular hypertension.

Saralasin infusion and blood pressure response: Figure 1 depicts the effects of saralasin infusion on diastolic arterial pressure in both groups of patients. Infusion of the peptide caused a significant reduction in diastolic pressure (9 ± 2 mm Hg; $p < 0.01$) in the group with renovascular disease. In the group without renovascular hypertension the mean change in diastolic pressure was −1 ± 1 mm Hg (not statistically significant). Figure 2 shows the percent of responses within a given range of pressure and the cumulative percent below a certain change in pressure. In the group with renovascular hypertension diastolic pressure was reduced by 10 mm Hg or more in 45 percent of studies and by 5 mm Hg or more in 75 percent of studies. In contrast, in the group without renovascular hypertension diastolic pressure was reduced by 10 mm Hg or more in only 6 percent and by 5 mm Hg or more in only 12 percent. Because the reduction of 5 mm Hg produced the best discrimination between groups (17 percent misclassified; 5 of 20 with renovascular hypertension and 4 of 34 without renovascular hypertension) this value was used as the basis for a positive test. By this criterion, the true positive rate for the saralasin test in detecting renovascular hypertension was 75 percent and the false positive rate 12 percent. The false negative rate for the saralasin test was 25 percent and the true negative rate 88 percent.

Discussion

The development of specific peptide antagonists of angiotensin II has led to a direct test of the role of the renin-angiotensin system in clinical renovascular hypertension. Early experience with saralasin indicated

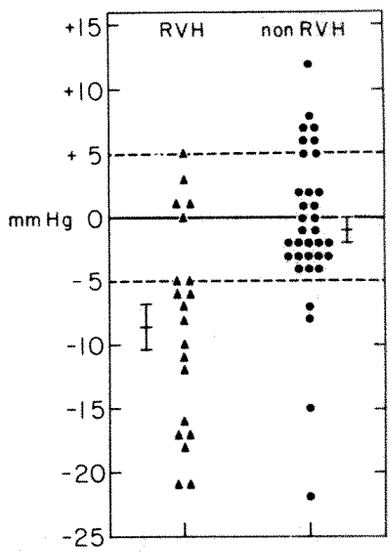

FIGURE 1. Effect of saralasin infusion upon diastolic arterial pressure in patients with (RVH) and without renovascular hypertension (non RVH). The mean value ± standard error of the mean for each group is indicated by the **horizontal bars.**

that nearly all patients with renovascular hypertension had reductions in pressure during infusion of the peptide especially when prepared by diuresis or a low salt diet.[4–9] It was even implied that patients who had no decrease in pressure with saralasin infusion need not be further evaluated for renovascular hypertension.[15] Subsequently, case reports[16–18] have documented the presence of surgically curable renovascular hypertension in patients with negative saralasin studies. Past studies have also documented that a small proportion of patients without renovascular hypertension—for example patients with presumed high renin essential hypertension[4,5] or secondary hypertension due to coarctation,[19] Cushing's syndrome[20] or renal transplantation,[21] also have depressor responses during saralasin infusion. If saralasin is to be used in screening patients for renovascular hypertension these secondary

The **bars** indicate the percent of patients responding with a given change in pressure. The **curves** present the cumulative percent of responses summated from left to right.

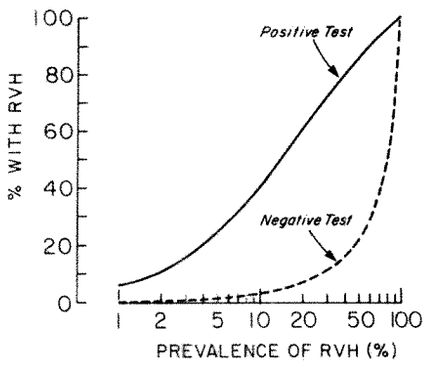

FIGURE 3. Calculated predictive value of positive or negative saralasin tests in relation to prevalence of renovascular hypertension (RVH) in a population to be screened.

forms of hypertension should be excluded as was the case in our series. In addition, renal arteriography and renal venous renin studies proved the lack of renovascular hypertension in all of our patients with false positive saralasin studies.

Significance of a positive or negative saralasin infusion test: In our series the saralasin test was positive in 75 percent of patients with proved renovascular hypertension, but 12 percent of those proved not to have renovascular hypertension had a false positive test. Should these estimates be applicable to more widespread screening for renovascular hypertension employing saralasin, the prevalence of renovascular hypertension becomes a factor in determining the predictive value of this test according to the Bayes theorem.[22] Figure 3 demonstrates the relation between prevalence of renovascular hypertension and the likelihood of renovascular hypertension if the saralasin test is positive or negative. It is apparent that if the prevalence rate of renovascular hypertension is low (for example, 2 percent), only 10 percent of positive saralasin tests will indicate renovascular hypertension because of the predominant number of false positive tests in the 98 percent of hypertensive patients without this condition. If renovascular hypertension is more prevalent, the usefulness of the saralasin test increases. However, the increasing fraction of false negative tests becomes more apparent.

Plasma renin activity versus change in blood pressure: Two recent studies have suggested that either the change in plasma renin activity during saralasin infusion or its absolute level at the end of infusion may assist in the discrimination between renovascular and essential hypertension.[23,24] Analysis of our data on plasma renin activity levels at midday, and before or after saralasin infusion showed that the change in diastolic pressure proved a better discriminator between renovascular and nonrenovascular hypertension than did absolute levels of plasma renin activity, change in absolute levels during infusion or percent change in these levels. The change in systolic pressure during saralasin infusion was also a poorer discriminator than the change in diastolic pressure. It is possible that variations in the protocol for study or the composition of the groups of patients account for these differences between our results and those reported.

The depressor action of saralasin may be related to the degree of sodium depletion before infusion. Although more drastic or prolonged diuresis may lead to a great percent of depressor responses in those with renovascular hypertension, it is likely that those without renovascular hypertension will also have more depressor responses[25,26]; that is, for more true positive responses there will be more false positive responses in screening for renovascular hypertension.

Clinical implications: Because of the partial agonist action of saralasin[27] it has been suggested that inhibition of converting enzyme reveals the role of the renin-angiotensin system in clinical hypertension to a greater extent.[28] This may be of little value in screening for renovascular hypertension if significant depressor responses to inhibition of converting enzyme occur in a large fraction of patients with normal renin hypertension and even in some with low renin essential hypertensives. Furthermore, the antihypertensive action of SQ-14225 and SQ-20881 may not entirely be explained by reduction in circulating angiotensin II, thus raising questions as to the specificity of these drugs.[29,30]

It may be argued that the saralasin test reveals significant information about the role of the renin-angiotensin system in hypertensive patients even if renovascular hypertension is not present. Such information may be useful in predicting responses to drug treatment, but controlled trials of this approach have yet to be published. At present, the saralasin test appears to be as useful as the intravenous pyelogram in screening patients for renovascular hypertension. The ultimate cost-effectiveness and risk-benefit considerations of the saralasin test in relation to other techniques in screening for renovascular hypertension remain to be established.

Pindolol in the Treatment of Hypertension: Systolic Time Intervals as a Predictor of Response to Beta Receptor Blockade

GARY D. PLOTNICK, MD, FACC

Baltimore, Maryland

Seventy-two hypertensive patients were treated with pindolol, a beta adrenergic blocking drug with intrinsic sympathomimetic activity. Serial measurements of systolic time intervals were utilized (1) to determine whether the therapeutic response to pindolol was predictable from pretreatment measurements, and (2) to assess changes in cardiac function during a 15 week treatment period. Patients with an abnormal pretreatment ratio of preejection period to left ventricular ejection time (PEP/LVET) of greater than 0.42 were less likely to respond with a decrease in mean blood pressure of greater than 10 percent (8 of 22) than were patients with a normal (0.42 or less) pretreatment PEP/LVET ratio (33 of 50) ($p < 0.05$). Patients with low renin hypertension were as likely to respond as patients with normal renin hypertension. All three patients with high renin hypertension responded to pindolol. When patients with high renin hypertension were excluded, the systolic time intervals were a better predictor of response than was the renin classification. In patients with an abnormal pretreatment PEP/LVET ratio who responded to pindolol, treatment resulted in an apparent improvement in cardiac function (that is, decrease in PEP/LVET ratio), presumably reflecting the influence of a reduced afterload.

Beta adrenergic blocking drugs are effective and widely used antihypertensive agents.[1-9] The mechanisms by which these drugs decrease blood pressure are complex and incompletely characterized. It is very likely that the effectiveness of beta adrenergic blocking agents as antihypertensive agents is influenced by the status of cardiac function and sympathetic activity prior to therapy.[7]

Pindolol (also known as LB-46 or Visken) is a potent beta adrenergic antagonist. It also possesses intrinsic sympathomimetic activity and as a result appears to cause less depression of cardiac function[10] and less bronchoconstriction[11] than do beta blocking agents without this action. Results from clinical trials[12-15] in Europe and Australia using pindolol alone or in combination with other antihypertensive agents have demonstrated that this compound significantly reduces blood pressure in more than 60 percent of the patients studied.

As part of a phase II clinical trial designed to document the antihypertensive effectiveness of pindolol, cardiac function was assessed by measuring serial systolic time intervals. This method was used for the purposes of (1) determining whether therapeutic response is influenced by, or predictable from, control values of blood pressure, heart rate or systolic time intervals, and (2) detecting changes in cardiac function that might occur during long-term administration of pindolol.

Methods

Patients: Criteria for inclusion in this study were: (1) stable uncomplicated hypertension of mild to moderate severity defined as a blood pressure greater than 150/100 and less than 230/120 mm Hg; (2) age less than 65 years; (3) presence of sinus rhythm and an electrocardiographic QRS duration of less than 100 ms; (4) absence of clinical evidence of congestive heart failure (cardiomegaly, basilar rales or ventricular gallop sound). Patients were excluded if they had concurrent disease, that is, bronchial asthma, chronic obstructive lung disease, chronic alcoholism, angina pectoris, insulin-treated diabetes, renal insufficiency (blood urea nitrogen greater than 30 mg/100 ml) and bradycardia (heart rate less than 50 beats/min). Only patients characterized as compliant (on the basis of pill counts and clinic attendance) were included.

Experimental design: The study was approved by the University of Maryland Human Volunteers Committee and each subject signed the approved consent form. All antihypertensive and diuretic medications were discontinued for at least 2 weeks before entry into the study and patients were advised to avoid excess salt intake. Initially, an oral placebo was administered three times a day for 3 weeks. Baseline measurements were determined at the end of this single-blind placebo washout period. Baseline systolic time intervals, heart rate, and blood pressure measurements were obtained while the patient was in the resting supine state. Blood pressure was measured with a mercury sphygmomanometer. Three blood pressure measurements were obtained at 2 minute intervals and these readings were repeated three times at 30 minute intervals. The baseline blood pressure was taken to be the average of these nine readings. Mean blood pressure was calculated as one-third pulse pressure added to the diastolic pressure.

Plasma renin activity: All subjects had blood drawn for determination of plasma renin activity on two occasions separated by 2 weeks during the period of placebo administration. A 24 hour urine collection for creatinine, sodium and volume measurement was completed at 8:00 a.m. on the day of the plasma renin activity test. Then, after the patient had been upright for 2 hours, a baseline blood sample was drawn at room temperature for renin activity determination. The plasma was separated in a refrigerated centrifuge and frozen as quickly as possible in order to minimize renin cryoactivation.[16] After the baseline blood sample had been taken, the patient received 80 mg of furosemide by mouth. Four hours later, the blood drawing and processing were repeated with the patient remaining upright most of the time.

Subjects were classified in low, normal or high renin subgroups on the basis of: (1) the results of the 24 hour urine sodium and baseline renin determinations compared with values on a nomogram constructed from urinary sodium and plasma renin data in 42 normal subjects who had been serially studied in identical fashion on normal, low and high sodium diets; and (2) the response of plasma renin activity to furosemide stimulation.[17] Patients' plasma renin activity was classified as "low" if the stimulated renin activity remained less than 1 ng/ml per h, "normal" if it was 1 to 5 ng/ml per h and "high" if it was greater than 5 ng/ml per h after administration of furosemide. As previously shown, the plasma renin activity values obtained by this method of categorization correlate well with those obtained during sodium restriction. Plasma renin activity was measured by a modification of Sealey's technique[18] in which 8-hydroxyquinolone solution and dimercapral were used instead of diisopropylfluorophosphate as angiotensinase inhibitors. Urinary sodium was measured by flame photometer.

Determinations of systolic time intervals: Simultaneous high frequency phonocardiogram, electrocardiogram and external carotid pulse tracing were recorded on an Irex multichannel recorder at a paper speed of 100 mm/s with 10 ms time lines. All recordings were obtained with the patient in a supine position with an approximately 30° elevation of the head and trunk. All studies were performed in the morning, at least 3 hours postprandially. Systolic time intervals were measured according to standard techniques.[19–21]

The left ventricular ejection time (LVET) was measured from the initial rapid upstroke to the incisura of the external carotid pulse tracing. Preejection period (PEP) was obtained by subtracting the left ventricular ejection time from the electromechanical systolic interval ($Q\text{-}S_2$) measured from the initial deflection of the QRS complex to the first high frequency component of the second heart sound. All patients had normal sinus rhythm and each value represents the mean of five consecutive cardiac cycles. The resultant mean systolic time intervals were corrected for heart rate using the linear regression equation of Weissler et al.[20] and are expressed in Tables I and II as indexes. Subsequent references to preejection period, $Q\text{-}S_2$ and left ventricular ejection time in the text refer to these rate-corrected values. The isovolumic contraction time was calculated by subtracting the left ventricular ejection time from the heart sound interval ($S_1 - S_2$). Uncorrected preejection period and left ventricular ejection time were used to determine the PEP/LVET ratio. This ratio is independent of heart rate, and the normal value ± 2 standard deviations is 0.34 ± 0.08.[21]

Analysis of treatment response: After the initial placebo washout period, patients were randomly treated with 15, 30 or 60 mg/day of pindolol given in three divided doses. Systolic time interval measurements, heart rate and blood pressure were recorded at 8 and 15 weeks of therapy. Patients whose pretreatment mean blood pressure decreased by 10 percent or more were classified as "responders"; those with lesser decreases were classified as "nonresponders." When control

Values shown are mean values ± standard deviation.
BP = blood pressure; I = index; ICT = isovolumic contraction time; LVETI = left ventricular ejection time index; PEPI = preejection period index; p = probability; PEP/LVET = ratio of preejection period to left ventricular ejection time. STI = systolic time intervals.

values were compared with measurements obtained during therapy for each patient, the systolic time intervals determined at the time of the lowest blood pressure were used.

To analyze and compare therapeutic responses in patients with normal versus those with abnormal left ventricular function, patients were divided into two groups dependent upon their baseline PEP/LVET ratio. Patients with a PEP/LVET ratio equal to or less than 0.42 (normal mean plus 2 standard deviations) constituted Group I (normal left ventricular function) and patients with a PEP/LVET ratio greater than 0.42 were included in Group II (abnormal left ventricular function).

Statistical analyses included paired and nonpaired *t* tests and chi square statistics.

Results

Patient characteristics: The clinical characteristics, renin status and baseline systolic time intervals of the 72 hypertensive patients are shown in Table I. The majority of patients were black men with a low or normal renin level. The mean systolic time intervals in our patients differed significantly from those of the normal subjects of Weissler et al.[19] in that the Q-S_2 interval and left ventricular ejection time were significantly shortened and the preejection period, isovolumic contraction time and PEP/LVET ratio were significantly increased. Fifty patients (69 percent of the total) had a PEP/LVET ratio of 0.42 or less (Group I) and 22 patients had a PEP/LVET ratio greater than 0.42 (Group II). There were no significant correlations among the clinical characteristics, renin status and systolic time intervals.

Responders to pindolol versus nonresponders: Of the 72 patients treated with pindolol, 41 (57 percent) were classified as responders and 31 (43 percent) as nonresponders. The clinical characteristics and systolic time intervals of these two groups are compared in Table II. There was no significant difference in the number of patients responding in each of the three dosage groups. There were also no differences in age, initial heart rate or Q-S_2 interval between responders and nonresponders.

A greater proportion of black than of nonblack patients responded to pindolol. Responders tended to have higher baseline systolic and mean blood pressures than did nonresponders. However, there were no correlations between race and baseline blood pressure or systolic time intervals. Responders had a significantly shorter mean preejection period and isovolumic contraction time and a significantly longer mean left ventricular ejection time than did nonresponders. Of the 50 patients in Group I (PEP/LVET ratio 0.42 or less), 33 (66 percent) were responders compared with only 8 of 22 pa-

TABLE II

Characteristics and Classification of Pindolol Responders Compared with Nonresponders*

Baseline Value	Responders (n = 41)	Nonresponders (n = 31)	p
Age (yr)	51 ± 9	48 ± 9	NS
Race			
Black	32 (67%)	16 (34%)	<0.05
White	9 (38%)	15 (61%)	
Baseline blood pressure (mm Hg)			
Systolic	157 ± 17	147 ± 13	<0.02
Diastolic	104 ± 7	102 ± 6	NS
Mean	122 ± 9	117 ± 8	<0.05
Baseline heart rate (beats/min)	72 ± 14	69 ± 11	NS
Daily dose (mg/day)			
15	15 (58%)	11 (42%)	
30	14 (61%)	9 (39%)	NS
60	12 (52%)	11 (48%)	
Baseline systolic time intervals			
Q-S_2I (ms)	540 ± 20	534 ± 21	NS
PEPI (ms)	131 ± 20	141 ± 19	<0.05
ICT (ms)	48 ± 21	60 ± 21	<0.025
LVETI (ms)	409 ± 22	395 ± 16	<0.005
PEP/LVET	0.36 ± 0.09	0.41 ± 0.08	<0.02
Group I (PEP/LVET ≤0.42)	33 (66%)	17 (34%)	<0.05
Group II (PEP/LVET >0.42)	8 (36%)	14 (64%)	
Renin group			
High	3 (100%)	0	NS
Normal	11 (58%)	8 (42%)	
Low	27 (54%)	23 (46%)	

* Values shown are mean ± standard deviation.
ICT = isovolumic contraction time; LVETI = left ventricular ejection time index; NS = not significant; p = probability; PEPI = preejection period index; PEP/LVET = ratio of preejection period to left ventricular ejection time.

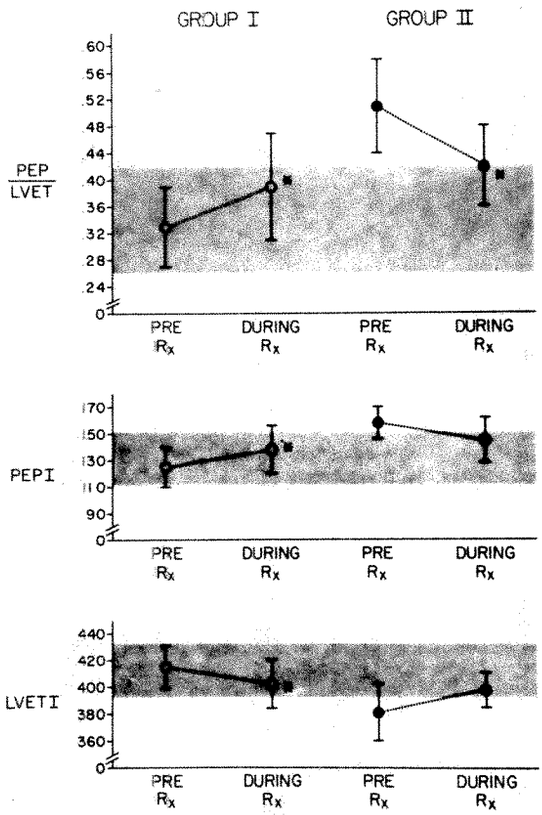

FIGURE 1. Systolic time intervals in Group I responders (n = 33) and in Group II responders (n = 8) before and during treatment (Rx) with pindolol. * = p <0.05. The **shaded areas** represent the normal mean values ±2 standard deviations.

tients (36 percent) in Group II (PEP/LVET greater than 0.42) ($p < 0.05$). Thus, patients with an abnormally increased pretreatment PEP/LVET ratio were less likely to respond than were patients with a normal PEP/LVET ratio.

High, normal and low renin groups: All three patients classified as having "high renin" were responders. Fifty-eight percent of patients with "normal" renin and 54 percent of those with "low" renin responded. One patient with high renin, 13 with normal renin and 36 with low renin were in Group I. There was no apparent relation between renin status and baseline systolic time intervals or response to therapy.

Effect on systolic time intervals: The systolic time intervals before and during treatment for responders are shown in Figure 1. The PEP/LVET ratio increased from 0.33 ± 0.06 to 0.39 ± 0.08 in the 33 responders in Group I ($p < 0.001$), but decreased from 0.51 ± 0.07 to 0.42 ± 0.06 in the 8 responders in Group II ($p < 0.05$). In Group I responders, the preejection period significantly increased, whereas the left ventricular ejection time significantly decreased with therapy. In Group II responders, the preejection period decreased and the left ventricular ejection time increased with therapy. There was no significant change in heart rate or $Q\text{-}S_2$ interval in either group with therapy. Although the mean values for systolic time intervals before and after therapy were not significantly different for nonresponders as a group, 11 of 15 "nonresponding" patients (73 percent) had an increase in PEP/LVET ratio.

DBP/PEP ratio: Before treatment, the ratio of diastolic blood pressure to preejection period (DBP/PEP) was higher for responders in Group I than in Group II. During therapy, the DBP/PEP ratio decreased in the responders in Group I, but was unchanged in the responders in Group II (Fig. 2). The mean DBP/PEP ratio ± standard deviation of 50 normal subjects studied in our laboratory was 858 ± 146.

Discussion

Although the majority of patients with systemic hypertension will respond to beta adrenergic blockade, minimal or no change in blood pressure occurs in 5 to 40 percent of patients treated with various beta blocking drugs.[1–3,5,6,12–15,22] Obviously it would be useful if the clinician could reliably identify those patients who would or would not respond to beta receptor blockade. In this study of pindolol, a beta adrenergic blocking drug with intrinsic sympathomimetic activity, we compared the 41 patients (57 percent) who showed a 10 percent or greater reduction in mean blood pressure (responders) with the 31 patients (43 percent) whose blood pressure did not decrease to this degree (nonresponders). Race, pretreatment blood pressure and systolic time intervals differed significantly in these two groups.

Predictors of blood pressure response to beta blockade: Essential hypertension, even when the clinical presentation is uncomplicated, is not a homogeneous clinical or hemodynamic entity. As a result, many potentially important factors could be considered possible predictors of clinical response to beta adrenergic blockade. Earlier studies had suggested that older hypertensive patients respond less well to beta blockade[23,24] and that renin levels are helpful in predicting clinical response.[7,23–27] However, other investigators found that these are *not* useful predictive factors.[5,25,26,28–31] In our 72 patients, the average age of responders and nonresponders did not differ significantly and the majority of patients (69 of 72, 96 percent) were classified as having normal or low renin hypertension. Because there were only three patients with high renin levels and there was no difference in response between the patients with normal and those with low renin levels, renin classification alone could not be used as a "therapeutic predictor" in this population.

Other factors suggested as predictors of response to beta adrenergic blocking agents include increased sympathetic activity,[7] high cardiac output[32,33] and labile hypertension.[32] Several recent studies have demonstrated a lack of correlation between decreases in blood pressure during treatment with beta blocking agents and control values of either peripheral resistance,[30,34] urinary catecholamine excretion[30,32,34] or initial cardiac output.[29,30,34–36] However, the influence of left ventricular function on therapeutic response and the changes in left ventricular function during therapy have not been extensively studied.

Influence of left ventricular function on therapeutic response: use of systolic time intervals: In choosing a method to study the influence of left ventricular function on response to beta receptor blockade, practical considerations require that the method be safe, relatively simple, inexpensive and widely available. The measurement of systolic time intervals fulfills all these prerequisites and is accepted as a useful noninvasive indicator of left ventricular function.[21] The ratio of the preejection period to the left ventricular ejection time (PEP/LVET) has been shown to be inversely related to left ventricular ejection fraction.[37] In addition, the rate of rise of left ventricular pressure measured indirectly (ratio of diastolic pressure to isovolumic contraction time [DBP/ICT]) provides a reliable index of maximal dP/dt (first derivative of ventricular pressure) measured

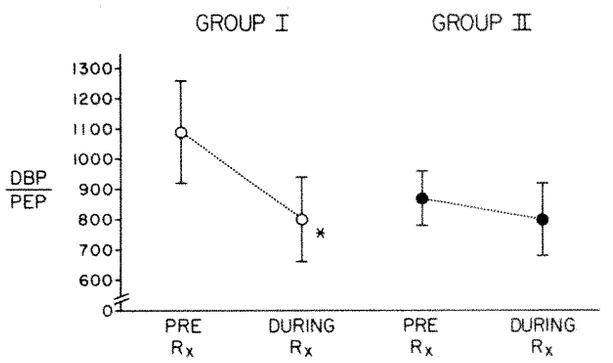

FIGURE 2. Ratio of diastolic blood pressure and preejection period (DBP/PEP) in Group I responders and in Group II responders before and during treatment (Rx) with pindolol. * = $p < 0.05$.

directly from the left ventricle.[38] In patients without intraventricular conduction delay, the preejection period (PEP) can be substituted for isovolumic contraction time (ICT) and is more easily measured.

Previous studies of systolic time intervals in asymptomatic patients with essential hypertension have demonstrated a wide range of values.[20,39–45] The findings of increased preejection period, decreased left ventricular ejection time and increased PEP/LVET ratio in our study group are similar to those of several previous reports.[40–43]

Although Tarazi et al.[40] reported that the prolongation of preejection period in patients with compensated hypertension is secondary to prolongation of the Q-S_1 interval with the isovolumic contraction time remaining normal, in our patients the isovolumic contraction time was significantly prolonged. The prolonged preejection period and isovolumic contraction time could be accounted for by diminished ventricular function (decreased dP/dt) or by the need to generate a higher pressure before aortic valve opening (effect of diastolic blood pressure).[42,45] Although Tarazi et al.[40] reported a correlation between preejection period and diastolic blood pressure, we were unable to substantiate this correlation. Therefore, we postulate that in our hypertensive patients impaired cardiac function, reflected by an increased preejection period, is common.

For analysis, we classified the patients into those with a normal pretreatment ventricular function (normal PEP/LVET ratio) and those with impaired function (abnormal ratio). Sixty-six percent of patients with a normal ratio responded to beta receptor blockade, whereas 64 percent of patients with an abnormal ratio failed to respond. The potential clinical utility of this finding is obvious.

Effect of pindolol on ventricular function: In addition to our observation that baseline systolic time intervals predict the likelihood of a satisfactory clinical response to beta blockade with pindolol, we were intrigued by the changes in systolic time intervals seen during pindolol therapy (Fig. 1). The 33 patients with a normal baseline PEP/LVET ratio who responded to pindolol (Group I) showed an increase in this ratio during treatment, whereas the small group of 8 patients with an abnormal PEP/LVET ratio who responded to pindolol (Group II) showed a decrease in this ratio (tendency to return to normal).

It is likely that the impact of pindolol on cardiac function depends on the relative contribution of three factors: (1) the hypotensive effect, (2) the beta blocking action, and (3) the intrinsic sympathomimetic activity. Recognizing the opposing effects of beta receptor blockade and intrinsic sympathomimetic activity, we suggest a hypothetical model that could explain the observed and directionally opposite changes in left ventricular function seen in patients who responded with similar decreases in blood pressure during pindolol therapy (Fig. 3). The DBP/PEP ratio was significantly higher in Group I responders than in Group II responders. Using this ratio as an indirect measure of left ventricular dP/dt, we propose that a higher DBP/PEP ratio reflects a relatively higher level of beta sympathetic "tone" (that is, greater cardiac beta adrenergic responsiveness). In turn, it might be expected that patients with higher beta adrenergic sympathetic "tone" would show changes in cardiac function during pindolol therapy that would predominantly reflect the influence of beta blockade with little contribution from intrinsic sympathomimetic activity. In contrast, in patients with lower beta sympathetic "tone" (lower DBP/PEP ratio), the intrinsic sympathomimetic effect of pindolol might make a relatively greater contribution and result in maintenance or improvement of overall left ventricular function. The decrease in the DBP/PEP ratio during pindolol treatment in Group I responders reflects the anticipated effects of beta receptor blockade. In the Group II responders, the DBP/PEP ratio did not change during treatment, presumably reflecting a balance between beta blocking and intrinsic sympathomimetic actions of pindolol. The overall decrease in the PEP/LVET ratio in Group II responders is presumed to reflect the effect of decreased blood pressure (afterload) with unchanged ventricular dP/dt.

This proposed model for interpreting our findings is consistent with the conceptual framework suggested by Wiedmann et al.[46] These investigators suggested that in hypertensive subjects there is "increased cardiovascular responsiveness to normal adrenergic outflow rather than sympathetic over-activity" and that "variations in sensitivity of cardiac and renal beta receptors . . . may modulate the effects of various sympatholytic agents as well as beta blockers."

Although the clinical significance of the intrinsic sympathomimetic activity of some of the newer beta receptor blocking drugs is still controversial, a recent review of pindolol suggests that the intrinsic sympathomimetic activity of this drug is clinically relevant.[47] An alternative explanation for our findings should also be considered. The lack of reduction in DBP/PEP ratio in patients in Group II might reflect the greater impact of afterload reduction in patients with poorer cardiac function.

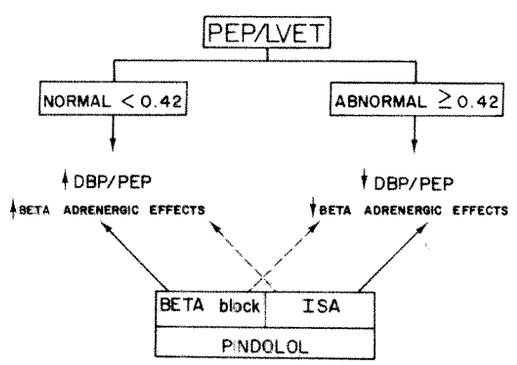

FIGURE 3. Proposed model to explain differences in response between patients with normal (<0.42) and abnormal (≥0.42) PEP/LVET ratio. BETA block = beta adrenergic blocking effect; DBP = diastolic blood pressure; ISA = intrinsic sympathomimetic activity; LVET = left ventricular ejection time; PEP = preejection period.

Clinical implications: Our study of serial systolic time intervals in 72 patients treated with pindolol for uncomplicated essential hypertension suggests that these easily obtained values may provide a predictive clue for clinical response to beta adrenergic blockade. Patients identified as having normal cardiac function (Group I) are more likely to respond to pindolol than are patients with abnormal cardiac function (Group II). Directionally opposite changes in systolic time intervals in the two subgroups suggest different mechanisms for changing cardiac function. Pindolol's dual action as a beta blocking agent with intrinsic sympathomimetic activity is proposed as a possible explanation, beta blockade effects predominating in Group I and sympathomimetic activity balancing the beta blocking effect in Group II. Further studies are needed to document the predictive value of systolic time intervals and to characterize further the unique changes in cardiac function seen during pindolol therapy.

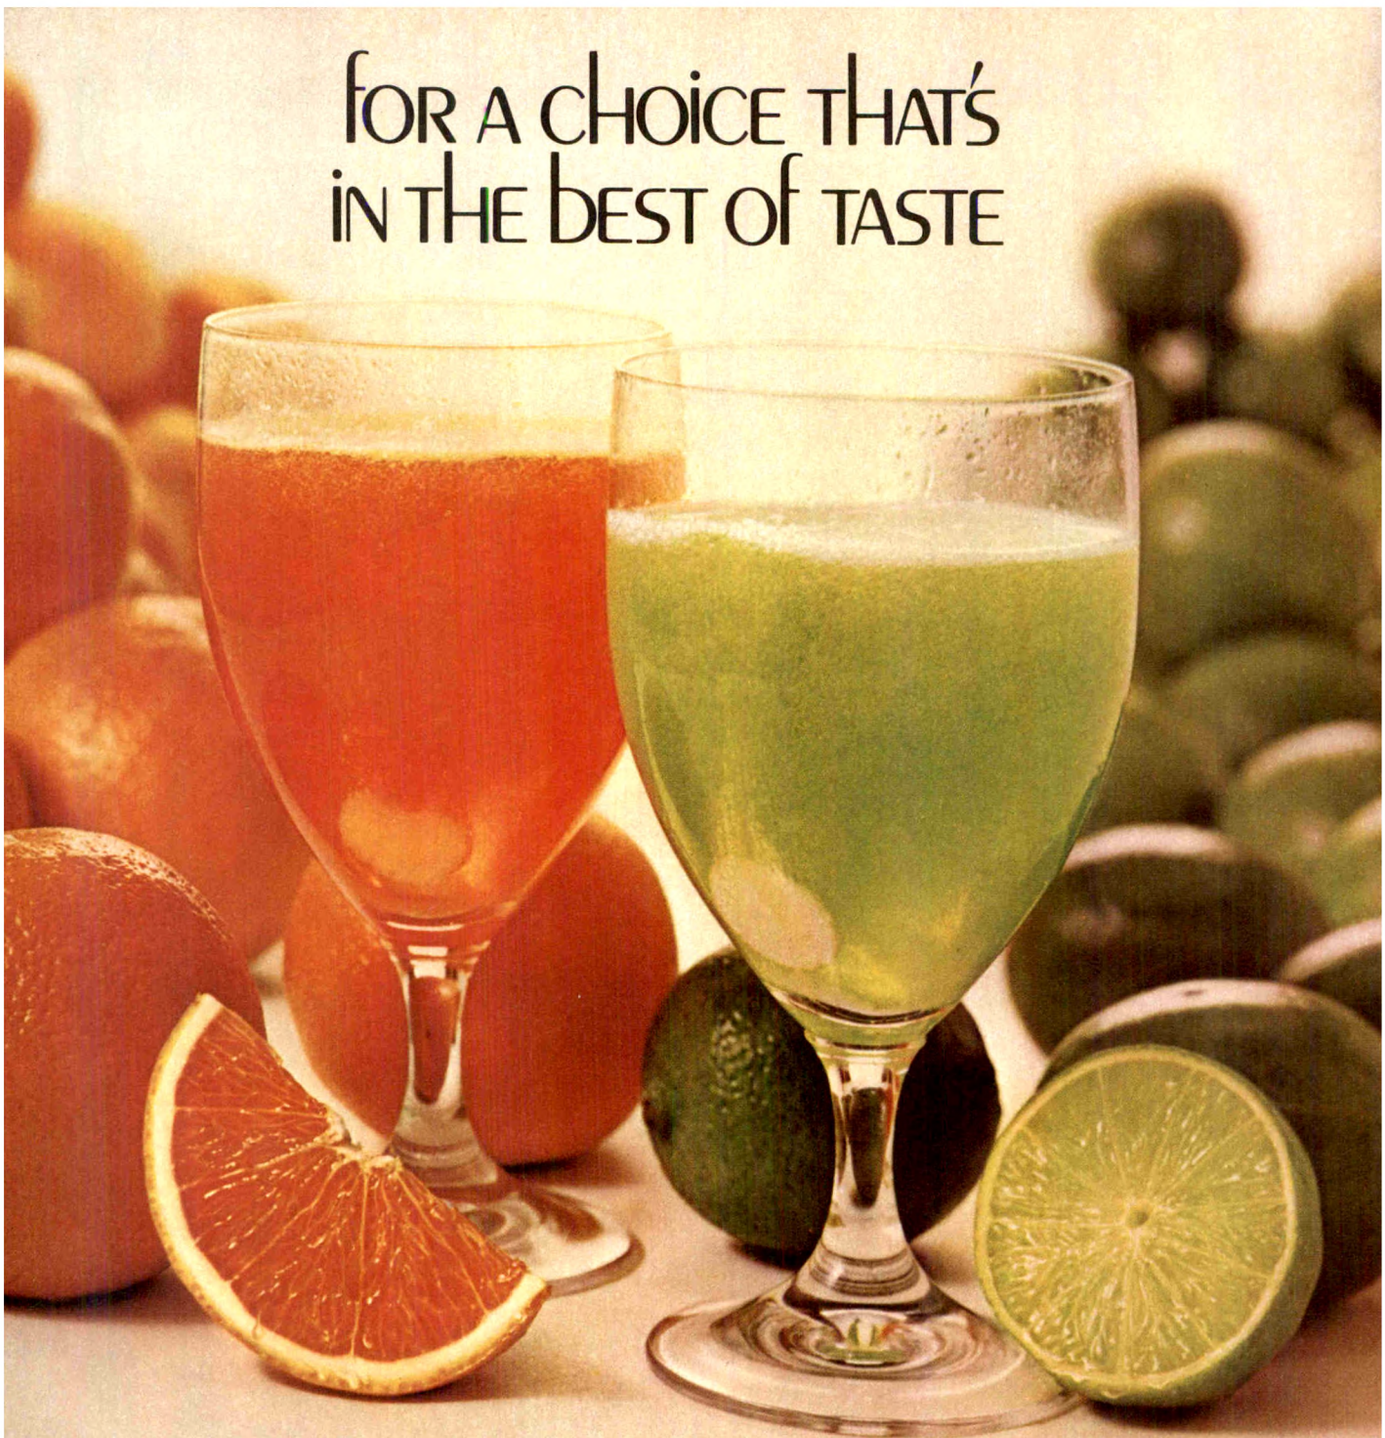
FOR A CHOICE THAT'S IN THE BEST OF TASTE



K-LYTE®

Each effervescent tablet in solution supplies 25 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
The best of taste for over a decade

K-LYTE® DS

Each effervescent tablet in solution supplies 50 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
Convenient once-a-day dosage

Prescribing Considerations

Indications: K-LYTE DS and K-LYTE are oral potassium supplements for therapy or prophylaxis of potassium deficiency. They are particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE DS and K-LYTE may also be useful for potassium replacement where digitalis intoxication results in cardiac arrhythmias.

Contraindications: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

Warnings and Precautions: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosages adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

Dosage and Administration: Adults: 1 K-LYTE DS tablet (50 mEq potassium) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily; 1 K-LYTE tablet (25 mEq potassium) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily. **NOTE: It is suggested that K-LYTE DS and K-LYTE be taken with meals and sipped slowly over a 5 to 10 minute period.**

How Supplied: K-LYTE DS effervescent tablets (orange or lime flavors) are available in cartons of 30 and 100. K-LYTE effervescent tablets (orange or lime flavors) are available in cartons of 30 and 250. All tablets are individually foil wrapped.

CONGESTIVE HEART FAILURE:
NO TIME TO INTRODUCE
VARIABLES.

If you wouldn't think of changing your brand of digitalis, shouldn't you think twice before switching from LASIX® furosemide to a substitute?

BRAND OF

Both digitalis and diuretics are almost always used in congestive heart failure. But both can cause serious cardiac arrhythmias.[1] *Digitalis, because digitalization is one of the most precarious titrations in all of medicine. And diuretics, because diuretic-induced hypokalemia increases the vulnerability to digitalis toxicity.*[2] *See warnings and precautions in the brief summary of product information on the next page.*

In serious congestive heart failure, the diuretic most frequently administered with digitalis is LASIX® brand of furosemide. However, the bioavailability of furosemide may be significantly altered by a change in tablet disintegrants and/or excipients.[3,4,5] And variations in the bioavailability of unlawfully-marketed furosemide tablets have produced unpredictable and serious clinical effects.[6]

Therefore, once the patient is stabilized on digitalis and LASIX®, changes in his cardiac regimen should be minimized.

LASIX®—the diuretic with the best record of success in all degrees of congestive heart failure.

LASIX® is the original brand of furosemide. It is LASIX® that established the standard for furosemide performance. It is LASIX® that is the subject of almost 6,000 published papers. It is LASIX® that has been used successfully in millions of digitalized patients over the past 14 years. And it is LASIX® that has a remarkable quality-control record—almost 8 billion tablets manufactured without a single product recall.

LASIX® tablets are available in a dosage strength to meet almost every patient need—20, 40 and 80 mg.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

LASIX®
FUROSEMIDE

ONE LESS VARIABLE IN THE DIGITALIZED PATIENT

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide). Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Because animal reproductive studies have shown that furosemide may cause fetal abnormalities, the drug is contraindicated in women of childbearing potential. Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use.

It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion: this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

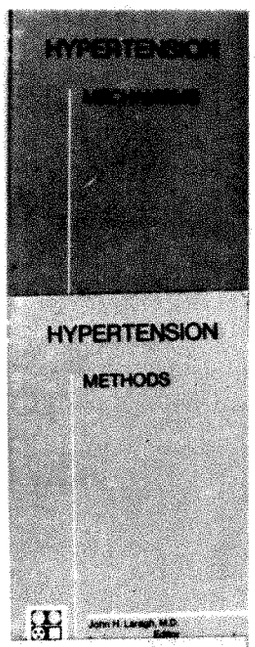
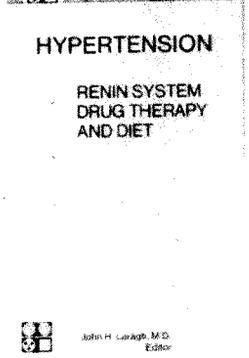
now available in paperback:
Laragh's HYPERTENSION MANUAL

You Can Now Buy This Famous Bestseller in Three Convenient Paperback Volumes Covering the Major Sections in the Original:





1. Mechanisms—**Clinical features and the physiologic and biochemical mechanisms of hypertension** (Partial Contents) ■ Arterial Pressure Regulation, Overriding Dominance of the Kidneys in Long-Term Regulation and in Hypertension ■ A Viewpoint Concerning the Enigma of Hypertension ■ The Control of Renin Release ■ The Control of Aldosterone Secretion in Normal and Hypertensive Man: Abnormal Renin-Aldosterone Patterns in Low Renin Hypertension ■ Physiologic Characteristics of Hypertension ■ Blood Pressure and Cardiac Performance ■ Neurogenic Factors in Human Hypertension: Mechanism or Myth? ■

505 pages, 150 figs. and tbls., index, $12.50

2. Methods—**The methodology involved in the evaluation of the physiologic parameters of high blood pressure.** ■ An Evaluation of Measurement Performance of Selected Blood Pressure Devices ■ Assay of Plasma Catecholamines. An Approach to Evaluating Altered Sympathetic Activity in Essential Hypertension ■ The Measurement of Plasma Renin Activity in Man ■ Measurement of Urinary Aldosterone Excretion in Man ■ Radioimmunoassay of Plasma Aldosterone ■ Searching Out Low Renin Patients: Limitations of Some Commonly Used Methods

120 pages, 50 figures and tables, index, $7.50

3. Renin System, Drug Therapy and Diet—**The principles of management and treatment, including the role of renin-aldosterone system in the strategy of treatment for high blood pressure. Also includes special sections of hypertensive drug therapy and low sodium diet.** ■ Vasoconstriction-Volume Analysis for Understanding and Treating Hypertension. The Use of Renin and Aldosterone Profiles ■ The Volume Factor in Low and Normal Renin Essential Hypertension. Its Treatment with Either Spironolactone or Chlorthalidone ■ The Antihypertensive Action of Propranolol. Specific Antirenin Responses in High and Normal Renin Forms of Essential, Renal, Renovascular and Malignant Hypertension ■ Antihypertensive Drug Therapy ■ Moderate Low Sodium Diet

105 pages, 25 figures and tables, index, $7.50

QUICK QUIZ

Fig. 1

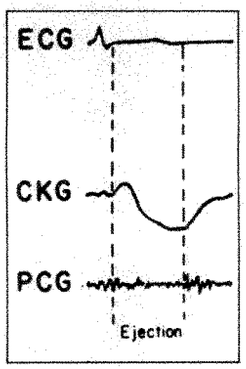

Fig. 2

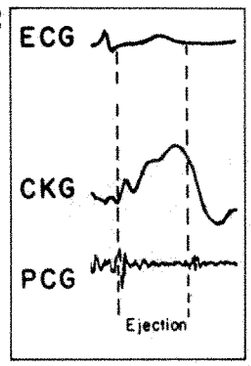

Fig. 3

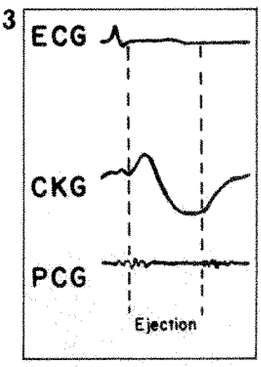

Fig. 4

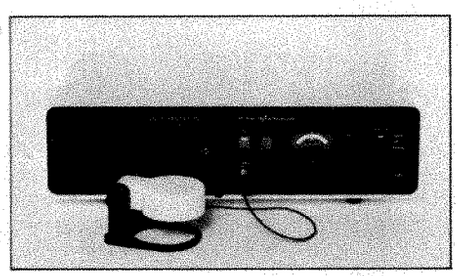

I. Figure 1 is a pre-stress CKG™ (Cardiokymograph) tracing of the left ventricle (V3 position), it demonstrates:*

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

II. Figure 2 is a two minute post-stress CKG (Cardiokymograph) tracing of the left ventricle (V3 position), on the same patient, demonstrating:

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

III. Figure 3 is a thirty minute post-stress resting CKG (Cardiokymograph) tracing of the left ventricle (V3 position), on the same patient, demonstrating:

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

IV. Figures 1, 2 and 3, taken together, demonstrate:

- ☐ A. stress induced ventricular wall motion abnormalities consistent with ischemia
- ☐ B. normal ventricular wall motion

V. According to recently published[1] data, the CKG (Cardiokymograph) stress test is:

- ☐ A. 98% sensitive—98% specific
- ☐ B. 59% sensitive—69% specific
- ☐ C. 74% sensitive—95% specific
- ☐ D. 40% sensitive—60% specific

VI. Figure 4 is a photograph of:

- ☐ A. CKG/700 (Cardiokymograph)
- ☐ B. a noninvasive device that provides an analog representation of wall motion
- ☐ C. a low cost, simple device to be used in conjunction with stress testing to enhance diagnostic accuracy
- ☐ D. all of the above

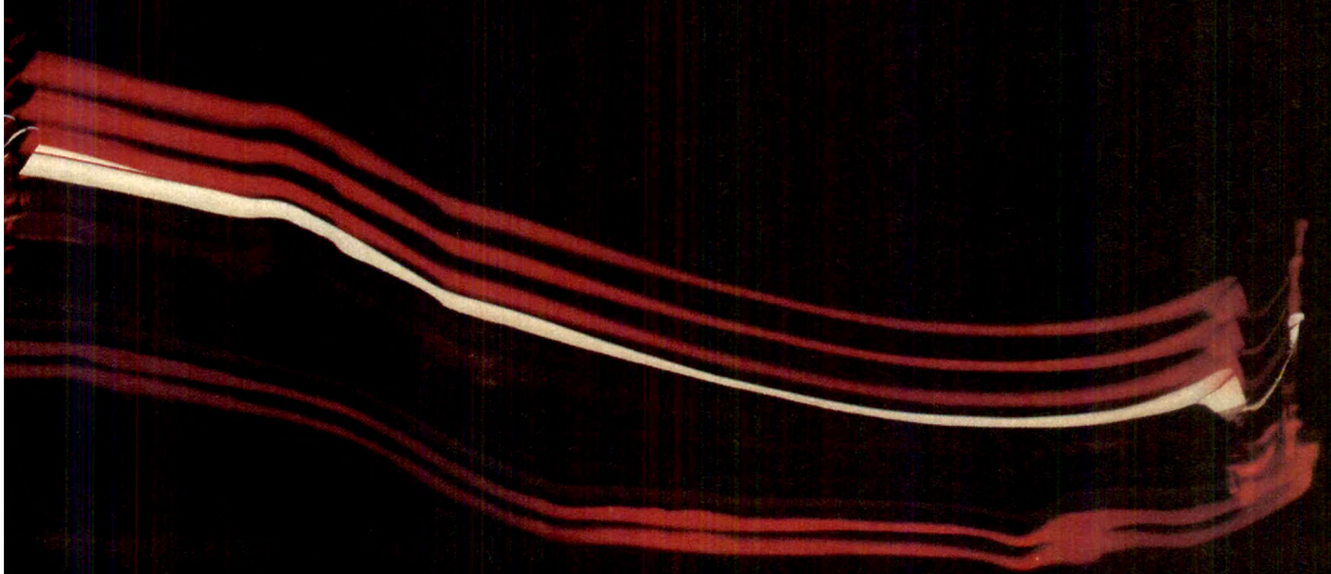
BRETYLOL®
(bretylium tosylate)

Unique antifibrillatory-antiarrhythmic effect
Unique mechanism of action
Unique safety: no cardiac depression



Bretylol® (bretylium tosylate), the unique new antifibrillatory-antiarrhythmic, provides lifesaving effects in the suppression of life-threatening ventricular arrhythmias unresponsive to lidocaine.

See last page of this advertisement for prescribing information.

BRETYLOL®
(bretylium tosylate):

Lifesaving potential in refractory ventricular arrhythmias

Unique antifibrillatory-antiarrhythmic effect

Studies in laboratory animals demonstrate that Bretylol significantly raises the ventricular fibrillation threshold with a consistency and magnitude that appears to be unique among antiarrhythmic agents.[1]

Bretylol (in conjunction with electrical cardioversion) frequently restores a normal sinus rhythm within minutes following intravenous injection in patients with ventricular fibrillation who have not responded to lidocaine.

Bretylol often controls ventricular tachycardia and other life-threatening ventricular ectopic rhythms, even when recurrent or refractory to lidocaine.

Clinically, Bretylol exhibits specific therapeutic effectiveness against refractory ventricular arrhythmias of various etiologies; for example, ventricular fibrillation and/or tachycardia associated with myocardial infarction;[2,6,9,10] open heart surgery,[7,8,10] and ischemic heart disease.[7] In one review of published experimental and clinical experiences with Bretylol,[11] the authors state, "clinical experience indicates that bretylium (Bretylol®) is frequently effective in the acute control of recurrent ventricular tachycardia or fibrillation resistant to other antiarrhythmic drugs... (and)...response of refractory ventricular arrhythmias to bretylium has been impressive."[11]

Unique safety

Unlike other antiarrhythmics, Bretylol does not depress cardiac function or exert a negative inotropic effect.[3]

There are no reports of Bretylol causing toxicity to any of the organs, including liver, kidney, heart, bone marrow, blood or central nervous system.

Therapy is generally well tolerated, and treatmen is seldom discontinued because of adverse effects.

Reductions in blood pressure (usually orthostatic may occur as a result of adrenergic blockade. If the patient is kept supine, the reduction in blood pressure is not usually clinically significant. Serious supine hypotension can occur in a few patients. Moreover, hypotension sometimes observed with Bretylol is not necessarily increased when the dosage is increased.

Unique cardiac effect

In laboratory studies Bretylol demonstrates a positive inotropic effect on the myocardium. Clinical reports confirm that Bretylol maintains cardiac output and does not depress myocardial function.[3]

Therefore, when used as an antiarrhythmic Bretylol should not interfere with the major therapeutic goal in the M.I. or post-open heart patient—the preservation of cardiac function.

It is recommended that the clinician consult the full prescribing information for dosage instructions and possible adverse effects prior to using Bretylol.

BRETYLOL bretylium tosylate

Brief Summary of Prescribing Information

CLINICAL PHARMACOLOGY—BRETYLOL (bretylium tosylate) suppresses ventricular fibrillation and ventricular arrhythmias. The mechanisms of the antifibrillatory and antiarrhythmic actions of BRETYLOL are not established. In efforts to define these mechanisms, the following electrophysiologic actions of BRETYLOL have been demonstrated in animal experiments:

1. Increase in ventricular fibrillation threshold.
2. Increase in action potential duration and effective refractory period without changes in heart rate.
3. Little effect on the rate of rise or amplitude of the cardiac action potential (Phase 0) or in resting membrane potential (Phase 4) in normal myocardium. However, when cell injury slows the rate of rise, decreases amplitude, and lowers resting membrane potential, BRETYLOL restores these parameters toward normal.
4. Increase in impulse formation and spontaneous firing rate of pacemaker tissue as well as increased ventricular induction velocity.

The restoration of injured myocardial cell electrophysiology toward normal, as well as the increase of the action potential duration and effective refractory period without changing their ratio to each other, may be important factors in suppressing reentry of aberrant impulses and decreasing induced dispersion of local excitable states.

BRETYLOL has a positive inotropic effect on the myocardium, but it is not yet certain whether this effect is direct or is mediated by catecholamine release.

BRETYLOL is eliminated intact by the kidneys. In various studies of BRETYLOL excretion, estimates of the terminal half-life have varied from about 5 to about 10 hours, with an even wider range in individual subjects (4 to 17 hours). Whether this represents true intrapatient variability or limitations of methodology remains to be determined.

Effect on Heart Rate: There is sometimes an initial small increase in heart rate when BRETYLOL is administered, but this is an inconsistent and transient occurrence.

Hemodynamic Effects: Following intravenous administration of 5 mg/kg of BRETYLOL to patients with acute myocardial infarction, there was a mild increase in arterial pressure, followed by a modest decrease, remaining within normal limits throughout. Pulmonary artery pressures, pulmonary capillary wedge pressure, right atrial pressure, cardiac index, stroke volume index, and stroke work index were not significantly changed. These hemodynamic effects were not correlated with antiarrhythmic activity.

Onset of Action: Suppression of ventricular fibrillation is rapid, usually occurring within minutes following intravenous administration. Suppression of ventricular tachycardia and other ventricular arrhythmias develops more slowly, usually 20 minutes to 2 hours after parenteral administration.

INDICATIONS—BRETYLOL is indicated in the treatment of life-threatening ventricular arrhythmias, principally ventricular fibrillation and ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine or procainamide. At this time, BRETYLOL should not be considered a first-line antiarrhythmic agent.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrhythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

CONTRAINDICATIONS—There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

WARNINGS—Administration of BRETYLOL regularly results in postural hypotension. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL should be avoided.

In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

USE IN PREGNANCY—The safety of BRETYLOL in human pregnancy has not been established.

USE IN CHILDREN—The safety and efficacy of this drug in children has not been established.

PRECAUTIONS—BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

Since BRETYLOL is excreted principally via the kidney, dosage should be reduced in patients with impaired renal function.

ADVERSE REACTIONS—Hypotension and postural hypotension have been the most frequently reported adverse reactions. Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route. Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

HOW SUPPLIED—NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP.

January 1980

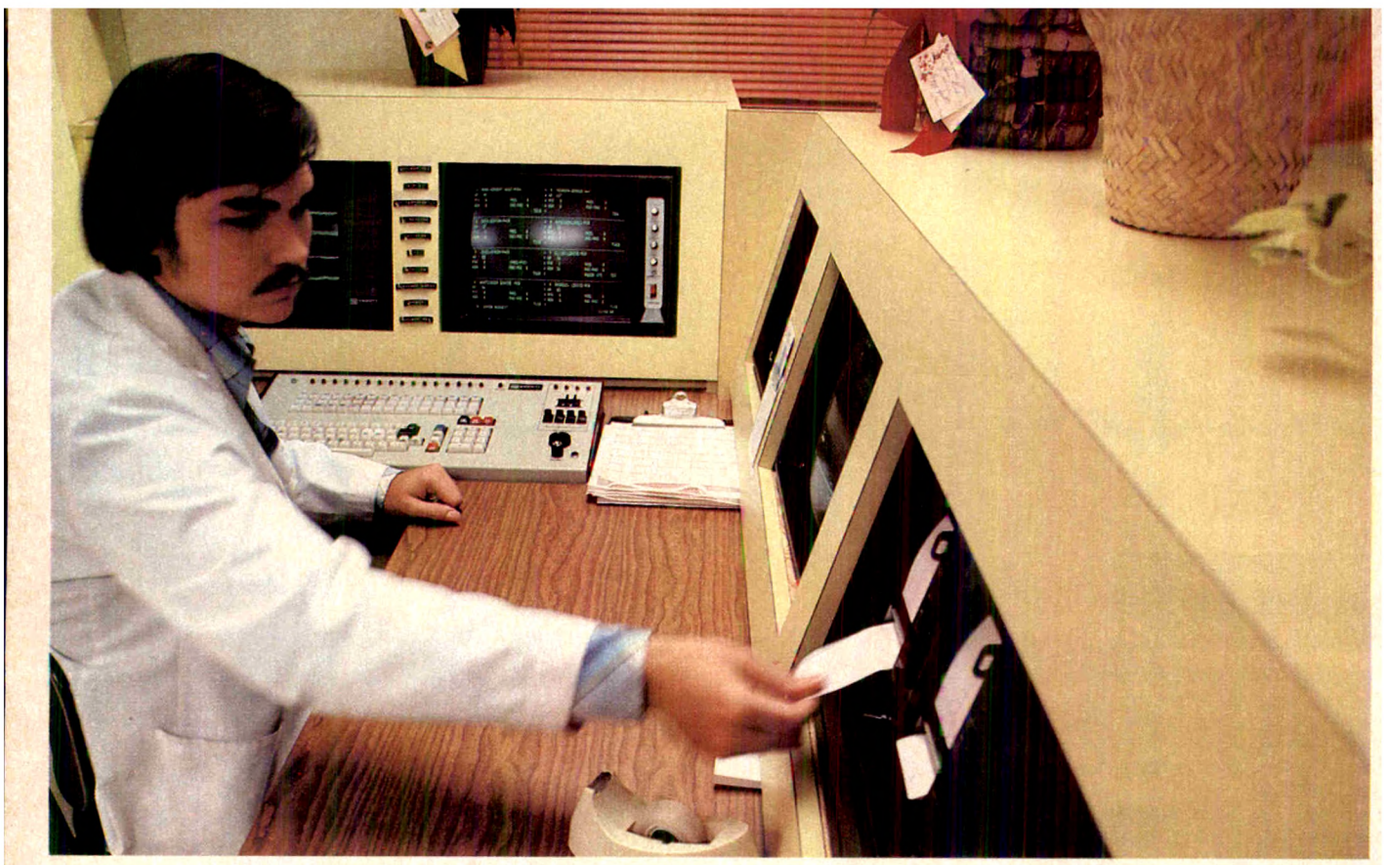
American Critical Care
(formerly Arnar-Stone Laboratories)
Division of
American Hospital Supply Corporation
McGaw Park IL 60085



This is Station 7...

This is Station 7 at Memorial City General Hospital in Houston, Texas, where Abbott's new "ACS" Arrhythmia Central is helping unit staff in the anticipation and prevention of life-threatening cardiac events.

While Station 7 is a general medical floor, many of the unit's patients are graduates of the Critical Care Unit, since many arrhythmias begin recurring days after a patient appears stable. Others monitored by the "ACS" are Post Op, or persons with suspected coronary problems who are not ill enough to be considered as CCU candidates.

In all cases, the 8-bed telemetry system watches for and trends arrhythmias that can foretell a possible, impending crisis. Treatment and drugs can be prescribed to reverse an arrhythmia pattern and block its recurrence.

The concept is working at Memorial City General. And Abbott's new "ACS" brings sophisticated and effective arrhythmia detection within practical reach of all hospitals, regardless of size.

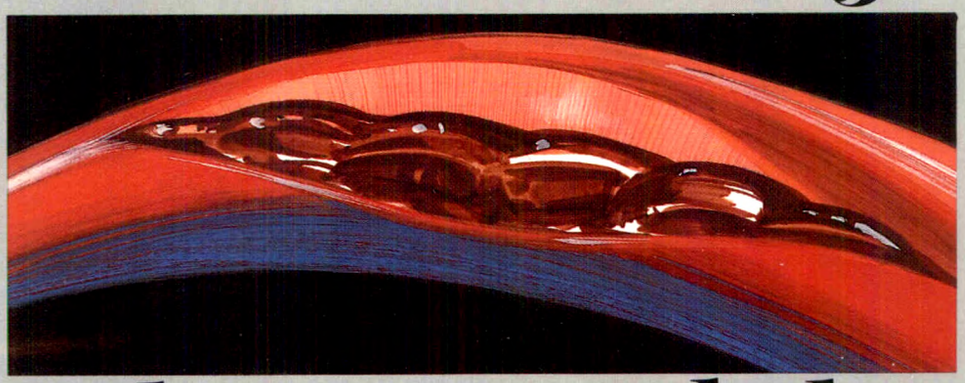
More detailed information is available free from:
Abbott Medical Electronics
8330 Broadway,
P.O. Box 12696
Houston, Texas 77017

Station 7 patients are monitored by means of battery-powered telemetry transmitters. Arrhythmias are more likely to occur with mobile, rather than supine, patients.

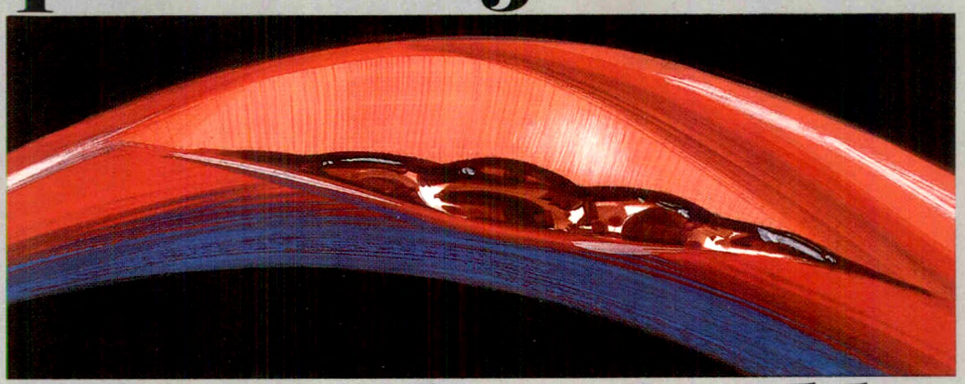
Ability to edit arrhythmia criteria if desired is a valuable feature of Abbott's ACS. Operator/System communication is via keyboard.

ABBOTT
Medical Electronics

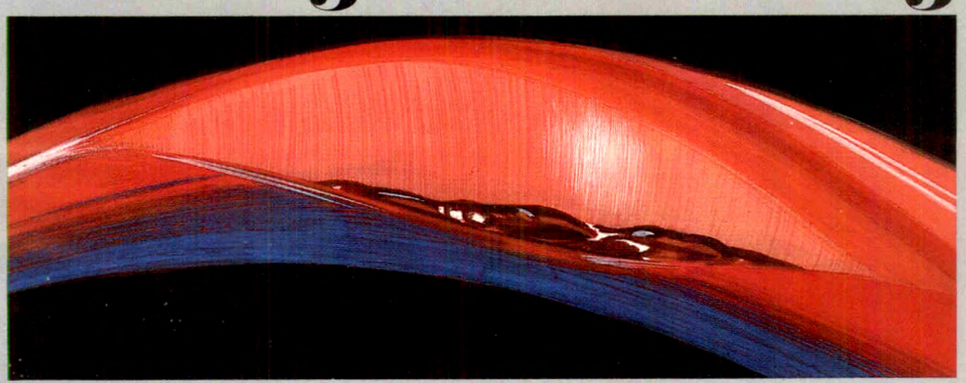
A life-threatening



pulmonary embolus



is being dissolved by



Artist's conception, based on changes in pulmonary angiography following Breokinase infusion.[1]

NEW

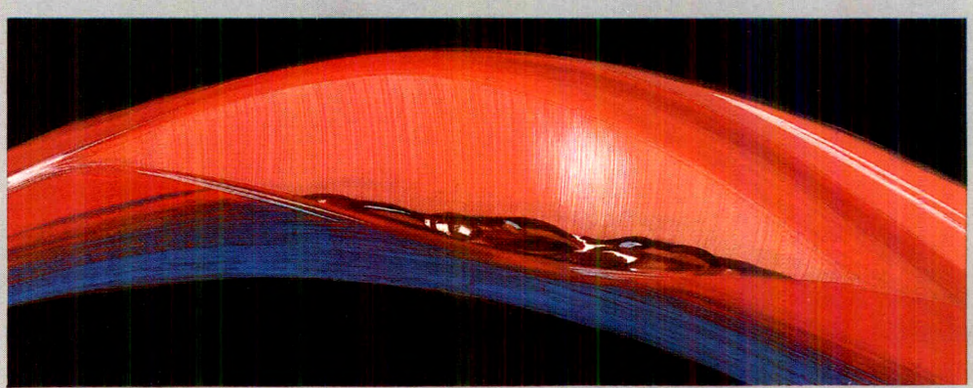
BREOKINASE®

(urokinase)

for injection

NEW BREOKINASE®
(urokinase)
for injection

Rapid and effective dissolution of pulmonary emboli.



- Proven by controlled clinical studies.[1]
- More rapid and effective than heparin alone during the first 24 hours after start of therapy.[2]

1. Sasahara AA, Hyers TM, Cole CM, et al: The urokinase pulmonary embolism trial. *Circulation* (Suppl II) 47:1-108, 1973.
2. Fratantoni JC, Ness P, Simon TL: Thrombolytic therapy: Current status. *N Eng J Med* 293:1073-1078, 1975.

Please see prescribing information on last page of this advertisement. It is important to pay close attention to WARNINGS and CONTRAINDICATIONS sections to minimize the risk of bleeding.

New Breokinase® is highly purified human protein.

- Lower incidence of fever.[3,4]*
- Can be used effectively in patients with recent streptococcal infections or high titers of streptococcal antibodies.
- Less risk of allergic reactions than streptokinase.†

Now urokinase therapy at lower cost

- Offers substantial savings to both hospital and patient.
- Convenient. Ask your Breon representative for a list of depots. There is one near you.

*Febrile episodes occurred in about 2-3% of urokinase-treated patients. A causal relationship to urokinase has not been established.

†In vitro and intradermal tests gave no evidence of induced antibody formation. However, the possibility of serious allergic reactions occurring cannot be excluded. There have been rare reports of relatively mild allergic reactions such as bronchospasm and rash.

3. Sasahara AA, Bell WR, Simon TL, Stengle JM, Sherry S: The phase II urokinase-streptokinase pulmonary embolism trial. *Thrombos Diathes Haemorrh (Stuttg)* 33:464-476, 1975.

4. Urokinase pulmonary embolism trial study group: Urokinase-streptokinase embolism trial. *JAMA* 229:1606-1613, 1974.

Doctor: Before prescribing or administering Breokinase® (urokinase for injection) please read the following product information.

BREOKINASE®

(urokinase) for injection

Breokinase (urokinase for injection) should be used only by physicians with adequate experience in the management of thrombotic disease in hospitals where necessary clinical and laboratory monitoring can be performed (see Warnings, Precautions and Dosage and Administration).

The physician should carefully assess the overall clinical status and history of the patient before beginning urokinase treatment. Urokinase produces more profound changes in hemostasis and a greater frequency of bleeding than heparin or oral coumarin anticoagulant therapy. Bleeding when it occurs is more severe and more difficult to manage. Such factors as patient's age, physical condition, and underlying bleeding tendency (as described under Warnings and Precautions) should be taken into consideration when the potential risk of serious hemorrhage is weighed against the potential benefits of urokinase treatment.

Indications

Breokinase is indicated for the thrombolytic treatment of:

—acute massive pulmonary embolism, defined as obstruction or significant filling defects involving two or more lobar pulmonary arteries or an equivalent amount of emboli in other vessels, as seen on pulmonary arteriography;

—pulmonary embolism accompanied by unstable hemodynamics, i.e., inability to maintain blood pressure without supportive measures.

The diagnosis of pulmonary embolism should be confirmed by objective means, preferably pulmonary arteriography.

Urokinase treatment should be started as soon as possible after diagnosis of pulmonary embolism, but no later than five days after onset. Under these circumstances, angiographic and hemodynamic measurements and perfusion lung scans demonstrate a more rapid improvement during the first 24 hours after initiation of therapy than with heparin therapy. However, it has not been established that urokinase treatment decreases morbidity or mortality compared to heparin therapy alone.

Contraindications

Thrombolytic therapy increases the risk of bleeding. The risk of hemorrhage in the conditions listed below should be weighed carefully against the anticipated benefits of urokinase therapy in each patient. The benefits and risks associated with urokinase therapy should be compared to the benefits and risks associated with other forms of treatment.

1. Surgical procedures within preceding ten days (including liver or kidney biopsy, lumbar puncture, thoracentesis, paracentesis, extensive or multiple cutdowns).
2. Intraarterial diagnostic procedure within ten days.
3. Ulcerative wound.
4. Recent trauma with possibility of internal injuries.
5. Visceral or intracranial malignancy.
6. Pregnancy and the first ten days post-partum.
7. Actively bleeding lesion of the gastrointestinal or genitourinary tract, or a condition with significant potential for bleeding (including ulcerative colitis, diverticulitis).
8. Severe hypertension.
9. Acute or chronic hepatic or renal insufficiency.
10. Uncontrolled hypocoagulable state (including coagulation factor deficiency, thrombocytopenia, spontaneous fibrinolysis, any purpuric or hemorrhagic disorder).
11. Chronic pulmonary disease with cavitation, e.g., tuberculosis.
12. Subacute bacterial endocarditis or rheumatic valvular disease.
13. Recent cerebral embolism, thrombosis or hemorrhage (within at least two months) to avoid risk of bleeding into infarcted cerebral tissue.
14. Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to locate or control.

Warnings

Bleeding: Activation of the fibrinolytic system with urokinase causes a more profound change in the hemostatic status of the patient than does anticoagulant therapy with heparin or coumarin agents. The objective of urokinase therapy is the production of sufficient amounts of plasmin to lyse intravascular deposits of fibrin; however, fibrin deposits which provide hemostasis, for example at sites of needle punctures, will also undergo lysis, and bleeding from such sites may occur. The possibility of bruising or hematoma formation, especially with intramuscular injections, is substantial during thrombolytic therapy. Unnecessary clinical or diagnostic procedures should be avoided. It is important that close attention be paid to this section and the Contraindications section in order to minimize the risk of bleeding.

Intramuscular injections should be avoided during urokinase therapy, as with heparin therapy, because of the high risk of hematoma formation. Bleeding may occur at sites of recent invasive procedures. Therefore, arterial punctures must be avoided before as well as during treatment with urokinase. If arterial puncture is *absolutely* necessary, the radial or brachial artery should be used and the femoral artery must be avoided. Arterial puncture should be performed with great care by an experienced physician and pressure should be applied for at least 15 minutes. This should be followed by the application of a pressure dressing, and the puncture site should be checked frequently for evidence of bleeding.

Venipunctures should also be perfomed as carefully and infrequently as possible. If bleeding from an invasive site occurs during urokinase infusion, but is not severe, treatment may be continued with close clinical observation. Local pressure and other measures should be initiated immediately.

Spontaneous internal bleeding that is not accessible for the application of pressure may also occur. The risk of spontaneous bleeding is greater in patients with pre-existing hemostatic abnormalities, including patients whose histories are suggestive of prior bleeding problems whether or not there are demonstrable abnormalities in platelet count, prothrombin time, partial thromboplastin time, or bleeding time. The relative risks and benefits of urokinase treatment must be carefully assessed in such patients before initiating treatment.

Plasmin degrades fibrinogen, Factor V, Factor VIII, and other proteins in addition to fibrin. The products of plasmin degradation of fibrinogen and fibrin (FDP/fdp) possess an anticoagulant effect which may make bleeding difficult to control.

If serious spontaneous bleeding occurs, the infusion of urokinase should be terminated immediately, and treatment instituted as described under Adverse Reactions.

Risk of Cerebral Embolism

Urokinase treatment of patients with atrial fibrillation or other conditions which predispose to cerebral embolism may be hazardous because of the risk of bleeding into the infarcted cerebral area.

Use of Anticoagulants

Concurrent use of anticoagulants with urokinase may be hazardous and is not recommended. Before beginning urokinase infusion in patients being treated with heparin, the effects of heparin should be allowed to decrease, as evidenced by a thrombin time of less than twice normal or an activated partial thromboplastin time (APTT) of less than one and one-half times normal. Similarly, heparin should be withheld for four hours following urokinase therapy unless the prothrombin time is in the normal range.

Rethrombosis has been observed after completion of urokinase treatment. In order to minimize this risk, administration of intravenous heparin followed by oral anticoagulant therapy is considered a necessary adjunct following urokinase therapy (see Dosage and Administration).

Use in Pregnancy

See Contraindications.

Use in Children

Safety and effectiveness of urokinase therapy in children have not been established; therefore, treatment of such patients is not recommended.

Precautions

Drug Interactions

Drugs that may alter platelet function, e.g., aspirin, indomethacin, and phenylbutazone, should be avoided during urokinase treatment. The interaction of BREOKINASE with other drugs has not been studied.

Laboratory Monitoring

In patients who have received heparin, the thrombin time or APTT should be measured prior to starting urokinase. (See Warnings.) Similarly, the prothrombin time should be monitored during and following urokinase therapy prior to instituting heparin. (See Dosage and Administration.) During urokinase administration, the levels of fibrinogen, plasminogen, Factor V, and Factor VIII are usually substantially decreased, and the level of fibrin and fibrinogen degradation products (FDP/fdp) is increased. Reduced fibrinogen and increased FDP/fdp result in a prolongation of the prothrombin time. Changes in these tests serve as confirmation of the existence of a lytic state. There are no data to indicate that alteration of dosage is required on the basis of these tests, although as a general rule the prothrombin time should not be allowed to increase above 30 seconds.

Urokinase infusion should be terminated immediately if serious bleeding occurs.

Adverse Reactions

Careful observance of the contraindications, warnings, and precautions to the use of urokinase is essential to minimize the incidence and severity of adverse effects.

Bleeding

Incidence

In controlled clinical trials of streptokinase and urokinase, severe bleeding (requiring a transfusion of greater than two units of blood) was seen in 4% of streptokinase patients and 6% of patients receiving urokinase. Several fatalities due to cerebral hemorrhage have occurred during urokinase therapy.

Spontaneous bleeding of a less severe degree has been observed during urokinase treatment at about twice the frequency as that occurring during heparin therapy. Oozing of blood from sites of skin puncture is frequent; therefore, all invasive procedures, especially arterial punctures and intramuscular injections, should be avoided and intravenous punctures kept to a minimum before and during treatment with urokinase.

A moderate decrease in hematocrit not accompanied by clinically detectable bleeding was observed in about 20% of patients treated with urokinase.

Management of Severe Bleeding

Urokinase therapy must be discontinued if serious bleeding occurs. Packed red cells are indicated for large blood loss. Plasma volume expanders (other than Dextran) may be used to replace blood volume deficit. Whole blood may also be used if it alone is available. The use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for urokinase has not been documented, but its use may be considered if the hemorrhage is unresponsive to blood replacement (see Warnings).

Allergic Reactions:

Urokinase is a protein of human origin, and *in vitro* as well as intradermal tests in humans gave no evidence of induced antibody formation. However, the possibility of serious allergic reactions (including anaphylaxis) occurring during its use cannot be excluded. There have been rare reports of relatively mild allergic reactions, e.g., bronchospasm and skin rash.

Fever:

Febrile episodes occurred in about 2-3% of urokinase-treated patients. A causal relationship to urokinase has not been established. Symptomatic treatment with acetaminophen rather that aspirin is usually sufficient.

Dosage and Administration

Preparation

Reconstitute each vial of Breokinase by aseptically adding 8.0 ml of Sterile Water for Injection, U.S.P. (It is important that *only* Sterile Water for Injection, U.S.P., *without* preservatives, be used. Bacteriostatic Water for Injection or other diluents should not be used.) Swirl gently to avoid foaming. **Do Not Shake.** Because Breokinase contains no preservatives, it should not be reconstituted until immediately before using. Any unused portion of the reconstituted material should be discarded.

Each ml of reconstituted Breokinase contains 31,250 C.T.A. Units of urokinase activity.

Dosing

Breokinase is Intended for Intravenous Infusion Only

Urokinase treatment should be begun as soon as possible after the occurrence of pulmonary embolism, and no later than five days after onset. A priming or loading dose of 2000 C.T.A. Units/lb (4400 C.T.A. Units/kg) of reconstituted Breokinase is given over a period of ten minutes. This is followed by a continuous infusion of 2000 C.T.A. Units/lb/hr (4400 C.T.A. Units/kg/hr) for 12 hours.

A constant infusion pump independent of all other intravenous systems should be used. Do not expose reconstituted solution to excessive heat, such as high intensity lights, during administration.

Anticoagulation Following Breokinase Treatment

At the end of Breokinase infusion, treatment with heparin by continuous intravenous infusion followed by oral anticoagulant therapy is recommended to minimize rethrombosis. Heparin treatment should begin 4 hours after Breokinase infusion, or sooner if the prothrombin time has returned to normal. See manufacturer's prescribing information for proper use of heparin.

How Supplied

Breokinase is supplied as a sterile lyophilized preparation. Each vial contains 250,000 C.T.A. Units of urokinase activity and approximately 0.9 millimols sodium phosphates. The vials should be stored at or below 4° C.

Episodic Drug Treatment in the Management of Paroxysmal Arrhythmias

BASIL MARGOLIS, MB, MRCP (UK)*
REGIS A. DeSILVA, MB, FRCP (C)
BERNARD LOWN, MD, FACC

Boston, Massachusetts

The use of maintenance medication in the treatment of episodic cardiac arrhythmia is often complicated by problems of patient compliance with therapy and adverse side effects. Furthermore, repeated hospitalizations and cardioversions are both costly and inconvenient. A method of intermittent drug therapy is described in which antiarrhythmic medication is taken only at the onset of an episode of arrhythmia. This approach was effective in terminating both supraventricular and ventricular arrhythmias in 24 of 32 patients and obviated the need for hospitalization and further treatment. In cases in which maintenance therapy was required because of the frequent occurrence of arrhythmia, periodic drug therapy was still of value in the treatment of breakthrough episodes. The use of intermittent drug therapy is a safe and effective approach to the management of episodic cardiac arrhythmia and, in addition, results in significant financial saving.

The introduction of direct current cardioversion and the availability of increasing numbers of antiarrhythmic drugs enable the modern clinician to terminate readily a variety of cardiac arrhythmias. The problem is frequently not how to abolish an arrhythmia, but rather how to prevent its recurrence. The clinician traditionally relies on prescribing an antiarrhythmic drug to be taken several times a day as prophylaxis against recurrence of episodic arrhythmia. However, when taken on a long-term basis, these medications may cause unwelcome and even serious complications. An attractive option is to use one or more antiarrhythmic medications in combination or in "cocktail" form only at the onset of an arrhythmia or even in anticipation of its possible development. This approach is applicable not only for atrial, but also for ventricular tachyarrhythmias, because it is now recognized that ventricular tachycardia in some patients need not significantly compromise cardiac output. Also, in the absence of myocardial infarction, ventricular tachycardia is less likely to degenerate into ventricular fibrillation.[1,2] The use of medications only as required avoids the problems of drug compliance[3] and is recommended by its inherent simplicity. When maintenance therapy is required because of frequently occurring arrhythmia, periodic drug cocktail therapy is still of value in the treatment of breakthrough episodes. This study was undertaken to assess the efficacy of such an approach.

Methods

Patients: Thirty-two patients with recurrent tachyarrhythmias were studied. The nature of the underlying arrhythmia was established by 24 hour ambulatory electrocardiographic monitoring. In certain cases, arrhythmia was provoked by exercise stress testing performed according to a Bruce protocol.[4,5]

Of the 32 patients, 22 were men and 10 women. Their ages ranged from 15 to 77 years (mean 47). All had experienced troublesome, symptomatic arrhythmias in the past and these arrhythmias had been treated unsuccessfully with nu-

TABLE I

Nature of Underlying Heart Disease in 32 Patients With Atrial and Ventricular Arrhythmias

Underlying Disease	Patients (n)	Atrial Fibrillation and Flutter	Supraventricular Tachycardia	Ventricular Tachycardia
Coronary artery disease	8	3	0	5
Mitral valve prolapse	2	2	0	0
Hypertension	5	4	1	0
Preexcitation syndrome	3	0	3	0
Functional murmurs	7	3	2	2
No structural heart disease	7	2	4	1

merous antiarrhythmic agents in adequate dosages. Fourteen patients had atrial fibrillation or flutter, or both, 10 had supraventricular tachycardia, and 8 had ventricular tachycardia. The associated underlying heart disease is shown in Table I.

Treatment protocol: Whenever possible, each clinically observed episode of arrhythmia was used as an opportunity to assess drug treatment. If the patient was in clinically stable condition, cardioversion was avoided and electrocardiographic monitoring was performed by telemetry trendscription using an American Optical Trendscriber.[6] This method permits continuous, on-line electrocardiographic monitoring in reduced format, thus enabling visualization of 30 minutes or more of information on one sheet of special recording paper. Carotid sinus massage and the Valsalva maneuver were attempted first for termination of both atrial and ventricular arrhythmias. If these maneuvers failed, an antiarrhythmic drug or drug combination was selected (as described later) and administered orally to the patient. A stop clock was simultaneously started and a continuous log of heart rate, rhythm and vital signs was kept. At the end of 1 hour, or at the estimated time of peak action of the drug, the vagal maneuvers were repeated. If after 2 hours patients had not responded to the drug, another antiarrhythmic agent was administered. In this manner, drug effectiveness as well as any adverse reactions were documented. If at any point the patient exhibited symptoms due to the arrhythmia, manifesting hypotension or chest pain, cardioversion was performed.

Selection of an antiarrhythmic agent was based on knowledge of the arrhythmia as well as known action of the drug. Quinidine was the drug of first choice for atrial fibrillation and atrial flutter, and digoxin or disopyramide was selected for supraventricular tachycardia. Procainamide was used as the agent of first choice for ventricular tachycardia because of its rapid onset of action. If slowing of the heart rate was desirable before reversion to sinus rhythm in patients with either atrial or ventricular arrhythmias, propranolol was added to the regimen. In addition, a sedative such as diazepam, 5 mg, was prescribed together with the antiarrhythmic agent or agents and this combination constituted the drug "cocktail." The final drug selection was determined by both therapeutic response and lack of adverse effects. The most common drug combinations we utilized for supraventricular and ventricular arrhythmias are shown in Table II.

TABLE II

Antiarrhythmic Drug Combinations Most Frequently Used in Terminating Atrial and Ventricular Arrhythmias in 32 Patients*

Supraventricular Arrhythmias	Ventricular Arrhythmias
Digoxin	Quinidine
Digoxin, quinidine	Quinidine, propranolol
Digoxin, quinidine, propranolol	Procainamide
Disopyramide	
Disopyramide, propranolol	
Disopyramide, digoxin	

* Diazepam (5 mg) was included with each drug or drug combination.

Follow-up treatment directions: Once a suitable drug cocktail was chosen, patients were discharged from the hospital with precise directions for its use. If the arrhythmia was supraventricular in origin, the patient was instructed on the use of right and left carotid sinus massage and the Valsalva maneuver. The latter was performed by sitting up in bed, grasping a pillow tightly with both arms, leaning forward and bearing down hard. If these maneuvers failed, the patient was to take the drug cocktail. If sinus rhythm was not restored by 1 hour, the patient was told to repeat the vagal maneuvers or the drug cocktail. Failure of the medication to terminate the arrhythmia or the development of symptoms such as chest pain or dyspnea constituted indications for notifying their physician.

As part of the follow-up study, a detailed questionnaire was completed by all patients to evaluate the efficacy of such treatment. Patients were asked about the frequency of arrhythmia, the time taken for the drug cocktail to abort a paroxysm and the side effect of the treatment. The number of hospital admissions before and after institution of the drug cocktail therapy was also assessed, as were the patients' attitudes toward self-medication.

Criteria for drug effectiveness: Assessing the efficacy of the drug cocktail posed several problems. The duration of the arrhythmia varied considerably for each patient and for each occasion they experienced an episode. Thus, there was no definitive way of determining whether the tachycardia would have terminated of its own accord had the drug cocktail not been taken. For the purpose of this study, therefore, the drug cocktail was arbitrarily judged effective if (1) the arrhythmia was aborted within 1 hour of administration of the medication, or (2) the number of hospital and emergency room admissions was materially reduced after the institution of drug cocktail therapy, or both.

The financial aspects of drug cocktail therapy were also considered. The savings obtained by dispensing with emergency room treatment, cardioversion and hospital admission were documented and the cost of maintenance antiarrhythmic medication was compared with the cost of intermittent drug therapy.

Results

Effectiveness of Therapy

In 24 of the patients (75 percent) drug cocktail therapy was deemed effective by the criteria chosen, namely, termination of the arrhythmia within 1 hour of taking

the medication, or a material reduction in the number of hospital and emergency room admissions, or both. In 16 of these 24 patients, the arrhythmias were terminated within 1 hour of administration of the medication. The mean effective time was 45 minutes. In the remaining 8 patients, the arrhythmia was terminated 1 to 3 hours after they had taken the drug cocktail; this result may or may not have been related to the medication. More striking was the marked reduction in hospital admissions and emergency room visits after the introduction of the intermittent medication program (Table III). Five of the patients with supraventricular arrhythmias were hospitalized between 10 and 23 times each before drug cocktail therapy was instituted. After the institution of therapy, none of these patients required hospitalization. Among the patients with ventricular tachycardia, one patient had had 20 hospitalizations and another 12 before drug cocktail therapy was prescribed. Thereafter, neither had a single hospitalization for ventricular tachycardia. Although the mean duration of symptoms among all patients before drug cocktail therapy was 15 years (range 1 to 40) and the mean duration of follow-up has only been 2.5 years (range 1 to 7), the improvement in the responders is still striking.

Of the 24 patients who responded to therapy, 9 patients (4 with atrial fibrillation, 3 with supraventricular tachycardia and 2 with ventricular tachycardia) received drug cocktail therapy alone; the remaining 15 patients required some form of maintenance antiarrhythmic medication as well as drug cocktail therapy for effective control. In a mean follow-up period of 2.8 years (range 2 to 7) none of the 9 patients who were treated solely with the drug cocktail regimen required emergency room treatment or hospitalization. Their arrhythmias were all terminated by drug cocktails taken at home. In the other 15 patients, breakthrough arrhythmias all responded to the drug cocktails; thus no change in maintenance medication was required and unnecessary hospitalization was avoided.

Eight of the 32 patients included in the study stopped the drug cocktail therapy either because it was deemed ineffective (5 patients) or produced unpleasant side effects (1 patient) or because the episodes of arrhythmia appeared to have abated without therapy (2 patients).

Atrial Fibrillation and Flutter

Of the 32 patients studied, 14 had paroxysmal atrial fibrillation or flutter. In 10 of these patients the arrhythmias were controlled by a variety of drug cocktails, including digoxin (0.25 to 0.5 mg), quinidine (200 to 800 mg) and propranolol (20 to 40 mg) either alone or in combination (Table II). The following case history is illustrative:

Illustrative Case 1: A 77 year old man had an 8 year history of paroxysmal atrial fibrillation. He had experienced about 10 episodes, all associated with central chest pain, that lasted from 2 to 12 hours. The paroxysms had resulted in several hospital admissions and as a result he had become depressed. He restricted many of his previous activities and was afraid to venture any great distance from his home or doctor. Physical examination was normal. The chest X-ray film showed a normal heart size and the electrocardiogram revealed right bundle block and left axis deviation. Twenty-four hour electrocardiographic monitoring confirmed runs of atrial fibrillation, and exercise stress testing revealed frequent atrial premature beats.

TABLE III

Mean Number of Hospital Admissions or Emergency Room Visits Before and After Introduction of Drug Cocktail Therapy

Arrhythmias	Patients (n)	Mean Number of Admissions	
		Before Therapy	After Therapy
Atrial fibrillation and flutter	10	3.4	0
Supraventricular tachycardia	8	9.9	0.1
Ventricular tachycardia	6	7.7	0.2

The patient was discharged on maintenance therapy of digoxin, 0.25 mg daily, and quinidine sulfate, 300 mg every 6 hours; we also prescribed a drug cocktail of digoxin, 0.25 mg; quinidine, 600 mg, and diazepam, 5 mg, to be taken at the onset of arrhythmia. Despite maintenance therapy, in the 2 years of follow-up study he experienced two episodes of paroxysmal atrial fibrillation that responded at home to the drug cocktail (Fig. 1). Since then he has regained tremendous

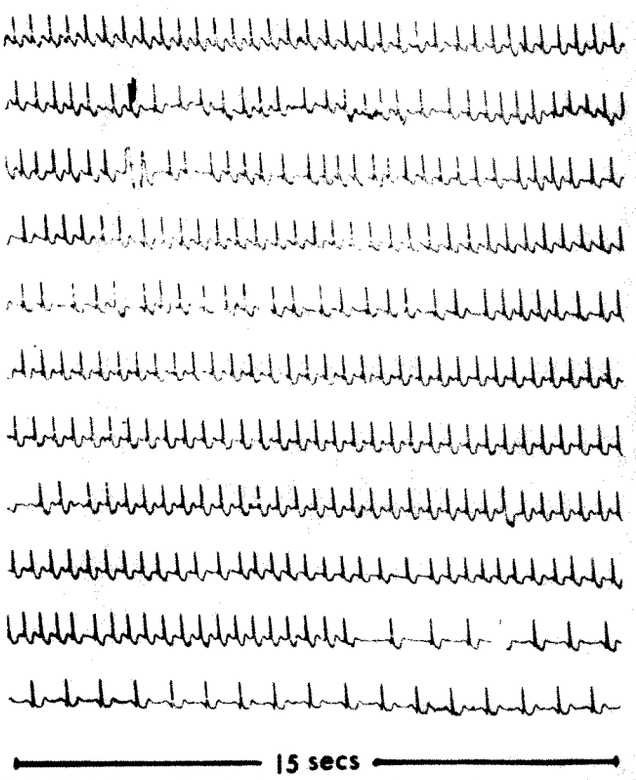

FIGURE 1. Case 1. Trendscription record of conversion of atrial fibrillation to sinus rhythm in a 77 year old man with paroxysmal atrial fibrillation. The resumption of sinus rhythm is noted in line 10, 50 minutes after ingestion of quinidine (300 mg), digoxin (0.25 mg) and diazepam (5 mg).

self-confidence and leads an active life once more, traveling abroad annually, armed with his drug cocktail.

Supraventricular Tachycardia

Ten of the 32 patients in the study experienced episodes of supraventricular tachycardia. In eight of these the arrhythmias were controlled with a variety of drug cocktails, including digoxin 0.25 to 1.0 mg, quinidine 200 to 600 mg; propranolol 20 to 60 mg and disopyramide 100 to 300 mg, either alone or in combination. The following case history is representative:

Illustrative Case 2: A 49 year old woman had had paroxysmal atrial tachycardia since the age of 8 years. Initially, the arrhythmia had terminated spontaneously, but during the preceding 3 years it had become refractory to routine antiarrhythmic agents and she had required several hospital admissions for treatment and cardioversion. Physical examination revealed an intermittent late systolic click, and echocardiography demonstrated prolapse of the posterior mitral valve leaflet. Twenty-four hour electrocardiographic monitoring confirmed the diagnosis of paroxysmal atrial tachycardia.

A drug cocktail consisting of digoxin 0.5 mg, propranolol 40 mg and diazepam 5 mg was prescribed to be taken at the onset of episodes of atrial tachycardia. In the ensuing 2 years the patient had four episodes of tachycardia; all were abolished by home treatment with the drug cocktail without contact with a physician (Fig. 2).

Ventricular Tachycardia

The third group consisted of eight patients with recurrent ventricular tachycardia, six of whom responded to drug cocktail therapy. The medications used were quinidine (300 to 600 mg), procainamide (1.0 to 2.0 g) and propranolol (40 to 60 mg), alone or in combination (Table II). The following case history exemplifies this experience.

Illustrative Case 3: A 48 year old investment executive had recurrent ventricular tachycardia 4 years after an inferior myocardial infarction. Coronary angiographic findings were normal. The patient had repeated bouts of ventricular tachycardia for 11 years, that occurred daily on occasions and lasted from a few minutes to several hours. The attacks, for which he was frequently hospitalized, were accompanied by dizziness and a feeling of nausea but were never associated with syncope. Numerous drug regimens and overdrive pacing were attempted without success. Physical examination and routine investigations were all normal. The electrocardiogram showed an old inferior myocardial infarction. Exercise was a significant factor in provoking his arrhythmia and this was confirmed on several occasions by exercise testing, which produced runs of ventricular tachycardia. Repeat exercise tests were performed on various medications and significant suppression of the ventricular tachycardia was noted with procainamide (Fig. 3). He was given instructions to take procainamide, 1 g, at the onset of any arrhythmia or prior to a situation that might provoke arrhythmia, such as a game of tennis or squash. He has subsequently done extremely well. No further hospitalizations have been necessary over the 7 years on this course of management and he now leads a very active life.

Cost Analysis

The costs of a visit to an emergency room, as well as the costs of a single cardioversion, a period of observation and admission to an intensive care unit for 24 hours of monitoring are listed in Table IV. If one considers, as an example, a fairly standard maintenance medication of digoxin (0.25 mg daily) plus quinidine sulfate (300 mg every 6 hours, the annual cost to a patient is $279. In contrast, a drug cocktail of digoxin (0.5 mg), plus quinidine sulfate (600 mg), taken four times in 1 year, for example, would cost the same patient only $2. Such an analysis would obviously apply only to those nine patients who were relying solely on drug cocktail

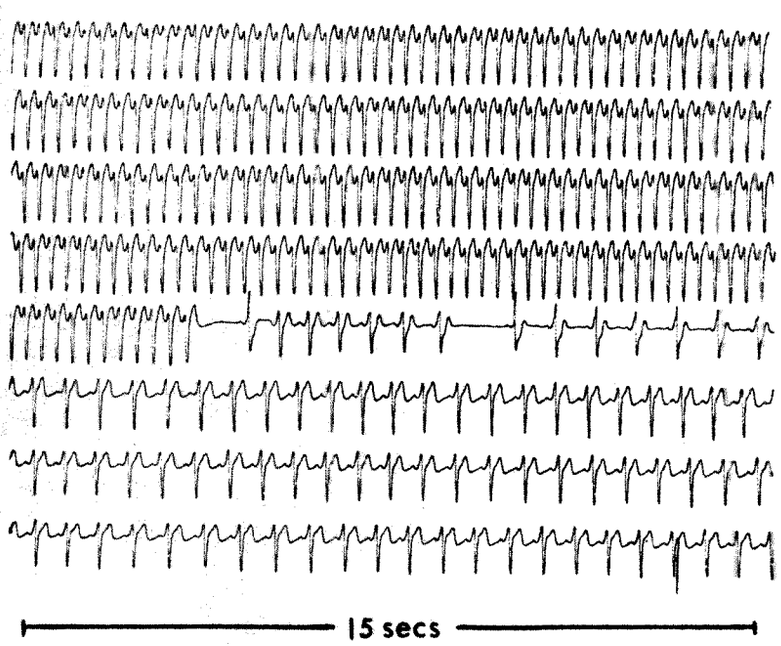

FIGURE 2. Case 2. Conversion to sinus rhythm of an episode of atrial tachycardia 20 minutes after ingestion of digoxin (0.5 mg), propranolol (40 mg) and diazepam (5 mg), in a 49 year old woman with a 40 year history of paroxysmal atrial tachycardia.

therapy. However, even among the remaining 15 patients the costs of emergency room treatment and hospital admission were avoided because their breakthrough arrhythmias were terminated at home with a drug cocktail. The tremendous financial savings thus become readily apparent.

TABLE IV

1979 Admission and Treatment Costs at a Boston Hospital

Emergency room visit plus 8 to 16 hours' observation	$120
24 hours in intensive care unit	$595
Electrical cardioversion	$ 77

Discussion

Indications: The philosophy of drug cocktail therapy is both simple and pragmatic. It aims at avoiding long-term maintenance therapy in patients with only episodic arrhythmias. Instead, medication is tailored to need. Such a form of treatment would not be applicable to patients with life-threatening arrhythmias. However, for those patients whose palpitations occur only at monthly or less frequent intervals and who are not significantly compromised hemodynamically, this approach has merit.

Additionally, drug cocktails can be utilized in patients receiving maintenance antiarrhythmic therapy who experience breakthrough arrhythmias. These patients on occasion exhibit episodic arrhythmia that can be controlled with an additional dose of the same medication used for maintenance therapy. This approach eliminates the need for repeated hospitalizations both to terminate the arrhythmia and to reshape the patient's primary antiarrhythmic program.

If the drug cocktail regimen is judged on its ability to terminate an arrhythmia within 60 minutes, we have shown it to be effective in half our cases. If efficacy is judged in terms of abolishing the need for emergency room treatment or hospital admission, this approach has been successful in three quarters of the cases. To date, no patient has had any complications. It should be emphasized that drug cocktail therapy is not used in patients who experience syncope or hypotension during episodes of arrhythmia. For example, patients with the Wolff-Parkinson-White syndrome, who experience rapid tachyarrhythmias, or those with ventricular tachycardia that is likely to degenerate into ventricular fibrillation are excluded at the outset. The treatment is reserved for patients who are symptomatic but who have no hemodynamic sequelae when the arrhythmia persists for several hours. Likewise, any patient who experiences dizziness or significant chest pain with an arrhythmia is advised to seek help promptly.

Advantages: There are several advantages to the approach we have used. The patient participates as an integral agent in the management process. Much of the psychologic disability from illness relates to the helplessness experienced in a situation that is neither understood nor correctable. The availability of a repertoire of prerehearsed activity in the face of a sudden onset of arrhythmia assuages anxiety and instills self-confidence. In the questionnaires completed by the patients, the overwhelming message was one of relief gained with the realization that the arrhythmias were not life-threatening. The responses also reflected the patients' newly won confidence that they were able to manage the arrhythmias on their own. Furthermore, we believe that the diminution of anxiety has been therapeutic in its own right. With removal of psychologic stress as a pro-

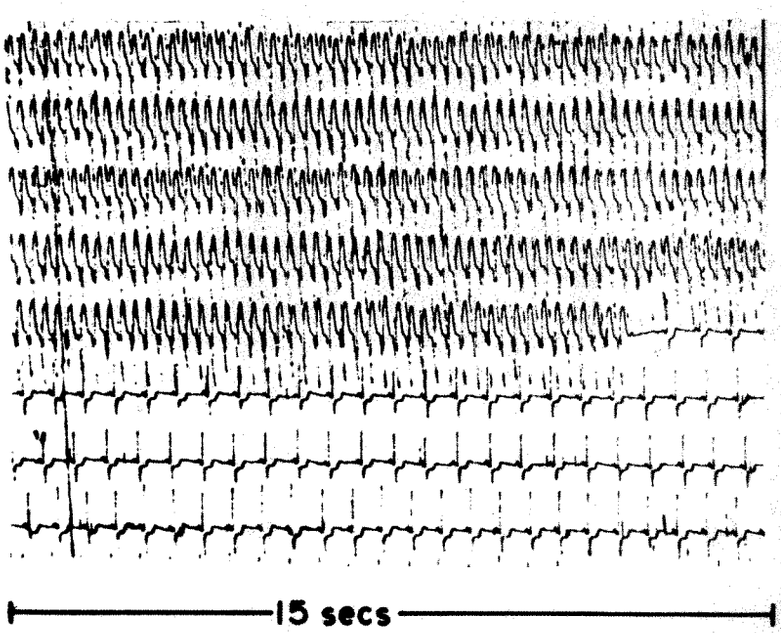

FIGURE 3. Case 3. Conversion to sinus rhythm of an episode of ventricular tachycardia 45 minutes after ingestion of procainamide (1.0 g) and diazepam (5 mg). The patient was a 48 year old man with an 11 year history of recurrent ventricular tachycardia.

voking factor of arrhythmia,[7] we believe that the frequency of paroxysmal tachycardias lessened in many of the patients. Another advantage is related to patient compliance with drug treatment regimens.[3] It is probable that patients with episodically occurring arrhythmias are less likely than patients with more persistent rhythm disorders to abide by a daily drug regimen during asymptomatic periods. However, the abrupt onset of arrhythmia is an immediate stimulus for initiating the medical regimen. The unpleasant side effects of antiarrhythmic medications can also be largely averted if the patient has to resort to drugs only occasionally.

Long-term therapy carries with it the problems of drug intolerance and toxic side effects such as thrombocytopenia with quinidine and procainamide-induced lupus erythematosus. Additionally, toxic interactions occur, such as that between digoxin and quinidine.[8] Although none of our patients experienced these problems, these considerations require close patient follow-up with frequent blood level estimations of these drugs. Intermittent dosing largely obviates these hazards and burdens. In patients requiring daily antiarrhythmic medication, the addition to the regimen of periodic treatment with a drug cocktail may permit a lower maintenance dosage than would otherwise be possible. Finally, the avoidance of inconvenient visits to the emergency room and the significant financial savings accrued add further to the appeal of our approach.

Mexiletine Therapy in 15 Patients With Drug-Resistant Ventricular Tachycardia

JAMES J. HEGER, MD
STANLEY NATTEL, MD
ROBERT L. RINKENBERGER, MD
DOUGLAS P. ZIPES, MD, FACC

Indianapolis, Indiana

Mexiletine therapy was administered to 15 patients with chronic and recurrent episodes of ventricular tachycardia or ventricular fibrillation. All patients were intolerant of or had arrhythmias resistant to conventional antiarrhythmic agents. At maximal dosages of mexiletine 2 patients had more than 90 percent reduction in frequency of premature ventricular complexes, whereas 11 patients had less than 50 percent reduction, as measured on 24 hour electrocardiographic recordings. Mexiletine was unsuccessful in preventing or abolishing ventricular tachycardia in 11 patients. Adverse side effects occurred in nine patients (60 percent) and were severe enough to necessitate discontinuation of therapy in six patients (40 percent). Side effects appeared to be dosage-related. Pharmacokinetic analysis indicated a mean elimination half-life of 12.6 ± 1.6 hours following oral administration of mexiletine. In the patients studied, mexiletine exhibited limited antiarrhythmic efficacy and was associated with frequent adverse side effects.

Mexiletine, a new antiarrhythmic agent recently released for use in Europe, currently is undergoing clinical investigation in the United States. Structurally and electrophysiologically similar to lidocaine, mexiletine has been shown effective in suppressing ventricular arrhythmias that occurred in patients with acute and chronic ischemic heart disease as well as in patients with other acute clinical conditions.[1–4] Reported side effects have been minimal. Preliminary pharmacokinetic data indicate that the oral form of mexiletine has good bioavailability and a relatively long half-life (10 to 24 hours), suggesting that it may be an excellent antiarrhythmic agent for long-term management of ventricular arrhythmias.[5,6] This report deals with the clinical evaluation of oral mexiletine in a study designed to assess its antiarrhythmic efficacy and to evaluate its pharmacokinetic properties in a group of patients with chronic, intractable ventricular arrhythmias.

Methods

Study patients: Fifteen patients, 10 men and 5 women with documented symptomatic ventricular tachycardia or ventricular fibrillation, were entered into the study. Their ages ranged from 28 to 76 years (mean 53), and the majority had arrhythmias related to chronic ischemic heart disease. These patients were considered for therapy with mexiletine because conventional agents failed to control the ventricular arrhythmia or produced intolerable side effects. Several patients also did not respond to a trial of investigational antiarrhythmic agents (Table I).

Episodes of ventricular tachycardia had produced syncope or presyncope in 12 patients. Frequent electric cardioversion was required in two patients, and two others had experienced cardiac arrest. Multiple asymptomatic episodes of ventricular tachycardia were recorded in the postinfarction period in two patients and after coronary arterial bypass grafting in one patient.

15	68M	Ischemic heart disease	+	+	+	–	–

+ = received drug; – = did not receive drug.

Records of prior antiarrhythmic therapy were reviewed to judge the adequacy of earlier drug trials. In the absence of limiting side effects, drug therapy was judged adequate (1) when the following doses had been administered: quinidine, 1,200 mg/day; procainamide, 3 g/day; and, where applicable, disopyramide, 600 mg/day; or (2) when plasma drug levels were within accepted therapeutic ranges.

Patients were excluded from the study if they had evidence of renal, hepatic or gastrointestinal disease because these conditions may adversely affect drug absorption or elimination. In addition, no patient had uncompensated heart failure, cardiogenic shock or any other long-term terminal illness. No other antiarrhythmic agent was administered during the study; however, six patients received digitalis for control of heart failure. No patient received concurrent therapy with narcotic analgesic agents because these drugs may interfere with mexiletine absorption.[5] Signed informed consent was obtained from each patient after the nature of the study and possible known risks had been explained.

Drug protocol: The protocol (Fig. 1) involved a single-blind sequential study and each patient served as his or her own control. The maximal dose of mexiletine was 300 mg every 8 hours in 12 patients and 400 mg every 8 hours in 3 patients.

Daily 24 hour electrocardiographic recordings were obtained in each patient. The electrocardiographic tapes were analyzed by a commercial firm to provide mean heart rate and total premature ventricular complex count for 24 hours. In addition, episodes of ventricular tachycardia, defined as three or more consecutive ventricular complexes at a rate greater than 100/min, were identified.

Patients were withdrawn from the study if the following developed: (1) second or third degree atrioventricular conduction block, (2) greater than 30 percent increase of P-R, QRS or Q-T intervals, or (3) intolerable side effects. Additionally, if patients exhibited an arrhythmia that required urgent therapy, the study protocol was discontinued.

Pharmacokinetic study: Heparinized blood samples were obtained 24 hours before and at 0, 1, 2, 3, 4, 6 and 8 hours after the last dose of a given dosage schedule. In addition, blood samples were obtained at 12, 16, 24, 32 and 40 hours after the last dose of mexiletine in those patients completing the protocol. These samples were centrifuged and the plasma was removed and frozen for subsequent gas chromatographic assay of mexiletine concentration.

Mexiletine half-life and elimination rate constant were determined from the terminal linear log (concentration) versus time curve after the last dose of mexiletine using least

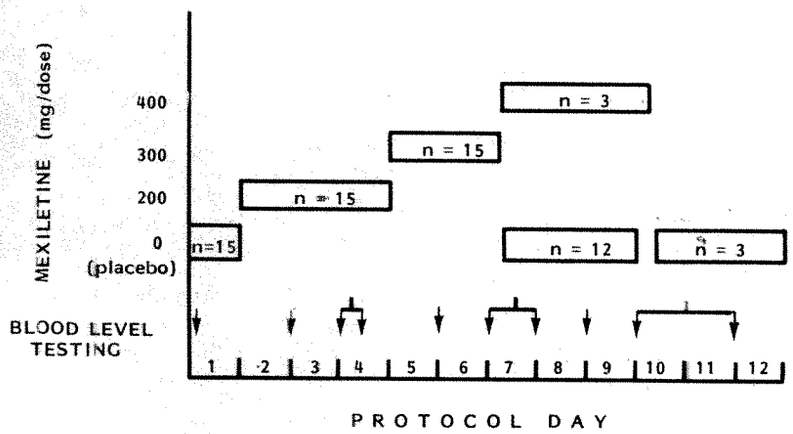

FIGURE 1. Outline of the protocol for mexiletine administration and assay of mexiletine blood levels planned for 15 study patients. Placebo was administered 24 hours before mexiletine was given and for 72 hours after the maximal mexiletine dosage level (300 mg in 12 patients, 400 mg in 3 patients). Mexiletine blood levels were also analyzed during steady state conditions at each dosage level.

TABLE II

Results of Mexiletine Therapy in 15 Patients

Case	Maximal Dose Mexiletine (mg/8h)	PVC Frequency/24h			VT		Lowest Mexiletine Plasma Concentration (μg/ml)	Cause of Premature Termination of Drug Trial	Adverse Effects

squares regression analysis. Area under the mexiletine concentration-time curve was calculated over the last 8 hour dosing interval of each dose regimen using the trapezoidal method. Plasma clearance of mexiletine was estimated for each dose regimen from the area under the concentration-time curve and the administered dose, assuming 90 percent bioavailability. Volume of distribution was determined by dividing the plasma clearance by the elimination rate constant.

Statistical analysis: The frequency of premature ventricular complexes during the control period was compared with their frequency at the maximal tolerated dose of mexiletine using Student's paired *t* test. The linearity of the relation between the area under the mexiletine concentration-time curve and mexiletine dose was tested using Student's *t* test applied to the univariate correlation coefficient. Plasma mexiletine clearance with the 200 and 300 mg dose schedules was compared using Student's paired *t* test. Null hypotheses were rejected if their statistical probability was less than 5 percent, using a two-tailed test in all cases. All values are expressed as mean values ± standard deviation.

Results

Antiarrhythmic effects of mexiletine (Table II): Continuous ambulatory electrocardiographic recordings adequate for analysis of frequency of premature ventricular complexes were obtained in 13 patients. Technical difficulties prevented accurate counts in two patients.

To assess antiarrhythmic efficacy, we compared the frequency of premature ventricular complexes measured during the pre-drug placebo control period with the frequency of premature ventricular complexes during treatment with the maximal dose of mexiletine. A 90 percent or greater reduction in frequency was observed in Patients 1 and 4, who had only 333 and 766 premature ventricular complexes/24h during the control period. The remaining 11 patients had either a slight decrease or an increase in frequency of premature ventricular complexes but no patient had more than 50 percent reduction in frequency. For the entire patient group, the mean frequency of premature ventricular complexes during the control period was 17,542 ± 12,327 complexes/24 hours compared with the mean value with the maximal mexiletine dose of 17,915 ± 15,030 complexes/24 hours. This difference was not significant. The mean lowest level of plasma concentration of mexiletine, available in 14 patients, was 1.39 ± 0.65 μg/ml.

The presence of ventricular tachycardia could be determined in 14 patients. It was present in nine patients during the pre-drug placebo control period. Mexiletine therapy did not successfully abolish ventricular tachycardia in any of these nine patients. No episodes of ventricular tachycardia were present during the placebo control period in five patients but they subsequently occurred in two of these patients during mexiletine therapy. Plasma concentrations of mexiletine ranged from 0.74 to 1.77 μg/ml during periods of recorded ventricular tachycardia. Drug therapy was prematurely terminated in two patients (Cases 3 and 10) because the appearance of symptomatic ventricular tachycardia required alternative treatment.

Seven patients completing the protocol had 24 hour electrocardiographic recordings during the post-drug placebo control period. The mean frequency of premature ventricular complexes was 23,427 ± 16,010, which was slightly but not significantly higher than the pre-drug placebo values.

Adverse effects (Table II): Of the 15 patients entering the study, 7 completed the entire protocol. Drug trials were prematurely terminated in two patients because ventricular tachycardia occurred during mexiletine therapy. Side effects, judged by the patient and physician to be severe, prompted discontinuation of the drug trial in six patients. Three additional patients had milder side effects that did not necessitate a change in therapy, and six patients reported no side effects.

The most common adverse reactions to mexiletine were nausea, vomiting, tremors and dizziness. One patient manifested a macular, erythematous skin rash on

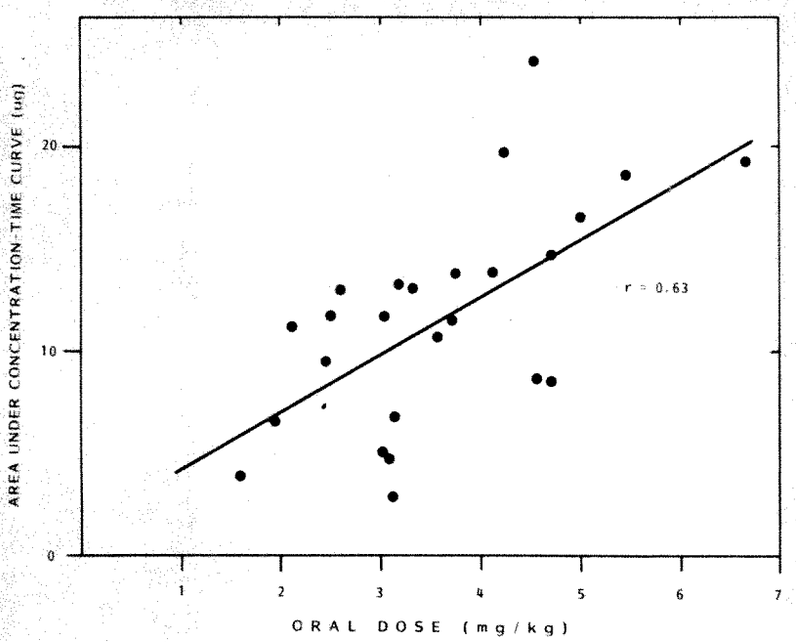

FIGURE 2. Area under concentration-time curve as a function of 8 hourly oral doses (in mg/kg body weight). The highly significant linear correlation ($r = 0.63$, $p < 0.001$) is suggestive of a first order elimination process.

the trunk, face and limbs that began 2 days after treatment was begun and disappeared several days after its discontinuation.

No patient exhibited changes in P-R, QRS or Q-T intervals during normal sinus rhythm. Additionally, no patient had any change in laboratory values that would indicate hepatic, renal or hematologic dysfunction.

Relation between plasma concentration and adverse effects: In six patients the side effects that necessitated discontinuation of therapy occurred shortly after an increase in mexiletine dosage. In these six patients the maximal mexiletine dose not associated with side effects produced a mean plasma concentration of 2.2 μg/ml at peak level and 1.2 μg/ml at the trough level. Therefore, adverse effects appeared to be related to dosage and plasma concentration of mexiletine.

Pharmacokinetics of mexiletine: The average fluctuation in the lowest level of plasma mexiletine concentration over the 24 hours before any dose change was 10 percent, confirming that steady state plasma concentrations had been achieved. The area under the plasma concentration-time curve for each dose regimen was linearly related to oral dose in mg/kg ($r = 0.63$, $p < 0.001$) (Fig. 2), suggesting first order elimination kinetics.[7] Average mexiletine plasma clearance with the 200 mg dose (335 ± 50 ml/min) was similar to that with the 300 mg dose (315 ± 40 ml/min) ($p > 0.5$). Furthermore, in three patients, there was no change in mexiletine plasma clearance with the 400 mg dose.

TABLE III

Pharmacokinetics of Mexiletine in the Seven Patients Who Completed the Protocol

	Mean	Range
Half-life (h)	12.6	10–14.4
Plasma clearance (ml/min)	363	221–619
Volume of distribution		
Liters/kg	5.56	3.9–9
Liters	403	275–578

The half-lives obtained from the terminal log concentration-time curves are shown in Table III, together with the other calculated pharmacokinetic variables. The correlation coefficients relating the logarithm of mexiletine concentration to time in these patients averaged 0.96 (range 0.90 to 0.99).

Long-term follow-up: Mexiletine was continued beyond the acute testing protocol for long-term therapy in Patients 4 and 6. Patient 4 received 300 mg every 8 hours for 10 months until recurrent ventricular tachycardia was noted in a routine ambulatory electrocardiographic recording. Mexiletine was then increased to 400 mg every 8 hours but side effects subsequently occurred and administration of the drug was discontinued. In Patient 6, administration of 400 mg of mexiletine every 8 hours was continued for 5 weeks but subsequent occurrence of side effects necessitated discontinuation of therapy.

Discussion

This study employed a controlled evaluation of the antiarrhythmic effects of mexiletine in 15 patients who (1) had ventricular tachycardia or ventricular fibrillation that recurred despite treatment with conventional agents, or (2) were intolerant to conventional antiarrhythmic agents. Analysis of antiarrhythmic effects with the maximal mexiletine dose revealed that 2 patients had a more than 90 percent reduction in frequency of premature ventricular complexes, whereas 11 patients had a less than 50 percent reduction. The mean frequency for these 13 patients was unchanged. Ventric-

ular tachycardia was not abolished in nine patients, whereas recurrent, uncontrolled ventricular tachycardia necessitated premature termination of mexiletine therapy in 2 patients.

Comparison with previous studies: Earlier studies have indicated better antiarrhythmic effects than those demonstrated in our trial. Talbot et al.[3] reported a 95 percent reduction in premature ventricular complexes in 43 of 59 patients treated with mexiletine, whereas while Campbell et al.[4] found a 50 percent or more reduction in 14 of 17 patients treated with oral mexiletine. Both reports indicate that mexiletine abolished ventricular tachycardia. Mexiletine has been found to be an effective agent for suppression of premature ventricular complexes and ventricular tachycardia in other studies as well.[6,8–19] In ventricular arrhythmias after myocardial infarction,[8,15] mexiletine demonstrated antiarrhythmic effects comparable to procainamide but was associated with fewer side effects. However, in our patient group; mexiletine demonstrated minimal antiarrhythmic effects as measured either by changes in frequency of premature ventricular complexes or suppression of ventricular tachycardia.

Side effects: Adverse effects had been most frequently reported with intravenous administration of mexiletine but initial reports[3,4] indicated these were less common during oral therapy. In our study, adverse effects occurred in nine patients (60 percent) and in 6 of these patients (40 percent) these effects were of sufficient severity to warrant discontinuation of therapy. We noted no instances of adverse cardiovascular effects such as bradycardia or arterial hypotension. The frequency of adverse effects we noted is similar to that reported in later studies. Campbell et al.[6] found severe adverse effects in 31 percent of patients, and Talbot et al.[9] reported a 29 percent incidence rate of severe adverse effects that necessitated some changes in therapy.

Therapeutic and maximally tolerated plasma concentrations: Antiarrhythmic effects of mexiletine were determined in our study at a time when trough plasma concentrations of mexiletine ranged from 0.6 to 3.1 μg/ml as measured in 14 patients. According to prior reports,[3,18,19] therapeutic plasma concentrations of mexiletine range between 0.75 and 2.00 μg/ml. Therefore, the poor antiarrhythmic response is not explained by a failure to achieve expected therapeutic plasma levels.

In the six patients with side effects that limited therapy, the mean mexiletine plasma concentration that was well tolerated was 1.2 μg/ml at the lowest level, while patients with no dose-limiting adverse effects achieved a plasma concentration of 1.5 μg/ml at the lowest level. It was not possible to determine the steady-state low levels of mexiletine at the time of severe adverse side effects but the maximal tolerated plasma levels in this study agree with the findings of Campbell et al.,[6] who suggested that adverse effects were most common when the lowest plasma concentrations exceeded 1.50 μg/ml. In our study four patients tolerated low level plasma concentrations greater than 1.5 μcg/ml but only two of the four had a more than 90 percent reduction in premature ventricular complexes; in the other two these complexes increased or ventricular tachycardia appeared. Our findings indicate there is both considerable interpatient variability in dose-response to mexiletine and a narrow toxic-therapeutic ratio of mexiletine.

Pharmacokinetics: Our data demonstrate that mexiletine appears to undergo elimination by a first-order pharmacokinetic process. This implies that at a given dosage regimen, plasma concentration is directly proportional to the size of the dose and elimination half-life is constant. The elimination half-life of mexiletine was 12.6 ± 1.6 hours. This value is similar to that reported by Prescott et al.[5] in six patients studied in a coronary care unit and is longer than the value found in normal volunteers of 9.3 ± 2.4 hours.[5] Thus, in the presence of cardiac disease, mexiletine half-life appears to be longer than in normal patients. If one assumes a bioavailability of 90 percent for oral mexiletine,[5] these pharmacokinetic data predict that an oral dose of 4.2 mg/kg every 8 hours should, at steady state, produce a mean plasma concentration of about 1.6 μg/ml, which is the mean effective plasma concentration reported by Talbot et al.[9]

Therapeutic implications: The observations on antiarrhythmic efficacy and adverse side effects of mexiletine in our patient group are disappointing. One factor that may account for the difference between our results and those of earlier trials is the nature of our patient group. In early studies, the majority of patients were treated for ventricular arrhythmias occurring within several days of acute myocardial infarction. In our study, nine patients had ischemic heart disease and all were studied more than 1 month after infarction, and the other 6 patients had a variety of cardiac disorders. In addition, all 15 patients had failed multiple trials of other oral antiarrhythmic agents in an attempt to control recurrent ventricular tachycardia. In a more recent study, Campbell et al.[6] noted similar findings in treating patients with chronic, recurrent ventricular tachycardia, despite adequate plasma concentrations of mexiletine. Therefore, mexiletine appears to have limited efficacy in the management of chronic, drug-resistant ventricular tachycardia and ventricular fibrillation and its use is associated with a relatively large incidence of adverse effects.

Addendum

Since this report, we have treated four additional patients with mexiletine. All had recurrent symptomatic ventricular tachycardia or ventricular fibrillation, or both, that was not controlled by conventional antiarrhythmic agents. Three patients had recurrence of symptomatic ventricular tachycardia while receiving other investigational agents. During a follow-up period of 1 to 6 months (mean 4.5 months), no patient has had clinical evidence of recurrence of ventricular tachycardia while receiving 200 to 400 mg of mexiletine every 8 hours. One patient required propranolol in addition to mexiletine. There were no apparent differences in any

clinical variables between these 4 patients and the first 15 treated patients that might account for the differences in clinical success with mexiletine treatment. We continue to believe that mexiletine has a limited role in treating patients with recurrent drug-resistant ventricular tachycardia.

Ventricular Ectopic Activity After Medical and Surgical Treatment for Recurrent Sustained Ventricular Tachycardia

IRVING M. HERLING, MD
LEONARD N. HOROWITZ, MD, FACC*
MARK E. JOSEPHSON, MD, FACC†

Philadelphia, Pennsylvania

Twenty-three patients with recurrent sustained ventricular tachycardia underwent Holter electrocardiographic monitoring to assess whether the frequency or grade, or both, of spontaneous ventricular ectopic activity was predictive of the therapeutic response to pharmacologic or surgical therapy as judged from electrophysiologic testing. Only infrequent, noncomplex ventricular ectopic activity was noted on Holter monitoring in six patients successfully treated with antiarrhythmic agents who subsequently have been free of recurrent sustained ventricular tachycardia. In only one patient did complex ventricular ectopic activity persist. In 11 (67 percent) of 16 patients in whom drug therapy failed (that is, in whom tachycardia was inducible), sustained ventricular tachycardia (7 patients) or other complex ventricular ectopic activity (4 patients) was noted during Holter monitoring on an ineffective regimen. However, 2 (20 percent) of these 11 and the remaining 5 patients (31 percent) in whom drug treatment failed showed greater than 90 percent suppression of all ventricular ectopic activity (other than ventricular tachycardia) on at least one ineffective regimen.

Eleven patients in whom drug therapy failed underwent aneurysmectomy and endocardial resection. Sustained ventricular tachycardia could not be induced postoperatively by programmed electric stimulation nor has it recurred spontaneously in any patient; however, 8 (72 percent) of these 11 had persistent complex ventricular ectopic activity on Holter monitoring. It is concluded that the response of ventricular ectopic activity on Holter monitoring to antiarrhythmic or surgical therapy does not predict therapeutic success in the treatment of recurrent sustained ventricular tachycardia.

The therapy for recurrent sustained ventricular tachycardia is often frustrating and unsuccessful despite the availability of numerous antiarrhythmic agents. Surgical procedures and specialized pacemaker devices have not previously met with widespread success. However, sophisticated electrophysiologic techniques, allowing the serial testing of antiarrhythmic agents and identification of the sites of origin of the tachycardia circuits, have recently provided a more rational approach to the management of these patients.[1–9] Although the ability to prevent the initiation of sustained ventricular tachycardia by pharmacologic or surgical therapy, or both, correlates with the presence of sustained ventricular tachycardia clinically, no data are available concerning the effects of these interventions on asymptomatic arrhythmia.

This study was designed to address the following questions: (1) Does therapy, which prevents the initiation of ventricular tachycardia, alter the frequency and grade of other ventricular ectopic activity when assessed with long-term electrocardiographic monitoring? (2) Can this effect on ventricular ectopic activity serve as a marker for the propensity for spontaneous sustained ventricular tachycardia to develop?

Methods

Patients: The study group comprised 18 men and 5 women ranging in age from 23 to 68 years (mean 56) (Table I). All patients had symptomatic ventricular tachycardia refractory to empirically designed antiarrhythmic regimens before their referral. Twenty-two of the 23 patients had coronary artery disease, including 14 (61 percent) with an angiographically defined ventricular aneurysm. One patient had previously undergone right ventriculotomy and infundibulectomy for repair of tetralogy of Fallot. All patients underwent electrophysiologic studies to assess the efficacy of several antiarrhythmic agents or surgery, or both, and were then followed up prospectively with a long-term regimen devised on the basis of the results of these studies.

Electrophysiologic studies: These studies were performed (after informed consent was obtained) with the patients in the nonsedated postabsorptive state. Multiple electrode catheters were inserted either percutaneously or by cutdown procedure and positioned in the heart under fluoroscopic guidance. Quadripolar electrode catheters were used when recording and stimulation from the site were required. The distal electrode was used for stimulation and the proximal pair for recording. Intracardiac recordings were filtered at 40 to 500 hertz and simultaneously displayed with two or three electrocardiographic leads on a multichannel oscilloscope (DR16, Electronics for Medicine, White Plains, New York). The data were stored on magnetic tape and later retrieved on photographic paper at speeds of 100 to 400 mm/s. Programmed electric stimulation was performed using a specially designed programmable stimulator and isolated current source (Bloom Associates, Ltd., Narberth, Pennsylvania). The stimuli were rectangular pulses 1 ms long and twice diastolic threshold during all studies.

The stimulation protocol during control and all subsequent studies included the introduction of single and double ventricular extrastimuli during normal sinus rhythm and during ventricular pacing at several cycle lengths, and ventricular pacing at cycle lengths of 600 to 250 ms for 15 to 60 seconds. This protocol has previously been described in detail.[4,6] In each patient, before pharmacologic or surgical therapy, ventricular tachycardia similar in morphologic features and rate to the spontaneously occurring arrhythmia could be reproducibly initiated with programmed ventricular stimulation.

Serial electrophysiologic studies were performed after the administration of various antiarrhythmic agents, including lidocaine, disopyramide, procainamide, quinidine, phenytoin and propranolol or combinations of these agents. During these studies the patients' clinical status was stable, serum electrolytes were maintained within the normal range and other medications were unchanged. If an agent prevented the induction of sustained ventricular tachycardia, blood levels were drawn and treatment with an antiarrhythmic regimen designed to provide similar long-term blood levels was initiated. Patients in whom no agent or combination of agents prevented the initiation of sustained ventricular tachycardia underwent endocardial mapping to localize the origin of the tachycardia circuit.[5] Eleven (69 percent) of the 16 patients in whom medical treatment failed thus studied underwent surgical resection of the aneurysm or scar and endocardial border at which the tachycardia was localized with intraoperative mapping.[10] Five (31 percent) of the 16 patients either refused surgery or were judged to have an inoperable condition and were treated with a medical regimen that made induction of ventricular tachycardia most difficult.

Continuous electrocardiographic monitoring: All patients underwent continuous electrocardiographic monitoring for at least 24 hours earlier by telemetry (B-D Electrodyne Computerized Arrhythmia Program) or by Holter monitoring after therapeutic intervention. The seven patients who responded to antiarrhythmic therapy underwent at least two

periods of continuous 24 hour electrocardiographic monitoring while they were on the medical regimen that prevented the initiation of ventricular tachycardia by programmed stimulation. Of the remaining 16 patients, 14 (88 percent) underwent continuous electrocardiographic monitoring on regimens that failed to prevent initiation of sustained ventricular tachycardia. All surgically treated patients underwent continuous electrocardiographic monitoring at least once and, in several instances, multiple times after postoperative electrophysiologic testing demonstrated that sustained ventricular tachycardia could no longer be induced. The frequency and complexity of ventricular ectopic activity was then assessed in all patients.

Results

Patients in whom antiarrhythmic therapy prevented initiation of ventricular tachycardia: In 7 (30 percent) of the 23 patients antiarrhythmic agents prevented the induction of sustained ventricular tachycardia (Table II). Procainamide was effective in four patients, procainamide and propranolol in one patient, phenytoin in one patient and disopyramide in the seventh. Each patient underwent continuous electrocardiographic monitoring during initial hospitalization 1 to 10 days after each electrophysiologic study. Virtual suppression of all complex and infrequent, noncomplex ventricular ectopic activity was noted on long-term electrocardiographic monitoring in six of seven patients. The frequency of ventricular ectopic activity ranged from 0 to 81 uniform ventricular premature depolarizations/h with mean frequencies ranging from 0.25 to 17.4/h. Only one patient (Case 5) continued to manifest bigeminal and trigeminal ventricular ectopic activity while on an effective regimen.

Sustained symptomatic ventricular tachycardia did not recur in the follow-up period of 3 to 34 months (mean 14) when the effective antiarrhythmic agent was maintained at the prescribed dosage. In three patients (Cases 1, 4 and 5) sustained ventricular tachycardia developed when antiarrhythmic therapy was interrupted either by the patient or the referring physician (Table II). Reinstitution of the prescribed dose resulted in continued absence of ventricular tachycardia. Patient 5 continued to manifest bigeminal and trigeminal ventricular ectopic activity even with the proved effective

Results of Holter Monitoring in Medical Responders

Case	Ineffective Regimen by Electrophysiologic Testing	Monitoring While VT Inducible	Effective Oral Regimen	Monitoring on Effective Regimen
1	Procainamide, 4 mg/min IV Procainamide, 6 mg/min IV Procainamide, 8 mg/min IV, and Propranolol, 20 mg q6h	60 VPDs (uniform) 1 h 30–60 VPDs/h (uniform) 30–60 VPDs/h (uniform)	Procainamide, 1 g q4h orally and Propranolol, 40 mg q6h	(1) 2 days post study→0 VPD/24 h (2) 8 days post study → 0–6 VPD/h (3) 11 days post study → 100 VPD/h Multiple episodes of sustained VT when dose of procainamide lowered to 750 q4h. No recurrence after institution of original effective dose.
2	Procainamide, 1,250 mg q4h	Frequent VPDs, salvos of couplets, triplets	Procainamide, 1,500 mg q4h	(1) 1 day post study → 0 VPD/24 h (2) 3 days post study → 0 VPD/24 h (3) 14 days post study→0–3 VPD/h (mean 0.25/h)
3	No antiarrhythmic agents	VT	Procainamide, 500 mg q4h	(1) 1 day post study → 0–54 VPD/h (2) 8 days post study → 0–81 VPD/h (mean 10/h)
4	No antiarrhythmic agents	VT	Procainamide, 500 mg q4h	(1) 10 days post study → 0 VPD/24 h (2) Cardiac arrest after procainamide discontinued by referring physician. On procainamide again, no recurrence
5	No antiarrhythmic agents	90–120 uniform VPDs/h	Phenytoin, 200 mg bid	(1) 1 day post study → bigeminy, quadrageminy (2) 11 days post study → (Norpace,® 150 mg tid, added) trigeminy (3) 1 yr post study → VT after missing dose of medication. No recurrence on reinstitution of phenytoin.
6*	No antiarrhythmic agents	VT	Disopyramide, 150 mg q6h	(1) 1 day post study → rare uniform VPDs (2) 2 days post study → 0/VPD/24 h
7	No antiarrhythmic agents Procainamide, 750 mg q4h	VT → VF 20 s episode of VT, 0–500 VPDs/h mean 69 VPDS/h	Procainamide, 1,250 mg q 4 h	(1) 2 days post study → 0–42 uniform VPDs/h (mean 17.4/h)

* Patient admitted medical noncompliance prior to this recording.
IV = intravenously; VPDs = ventricular premature depolarizations; VT = ventricular tachycardia.

antiarrhythmic regimen. Disopyramide was added by the referring physician, but it did not alter the frequency of the arrhythmia. The patient remained asymptomatic until 1 year after hospitalization when, after missing several doses of her medication, she had an episode of sustained ventricular tachycardia requiring direct current cardioversion. After reinstitution of her initial medication she continued to be asymptomatic over the ensuing 10 months.

Patients in whom antiarrhythmic therapy failed to prevent electrophysiologic initiation of ventricular tachycardia: In 16 (70 percent) of the initial 23 patients, ventricular tachycardia was inducible despite treatment with all antiarrhythmic agents (Tables III and IV). Five (31 percent) of these 16 did not undergo surgery (Table IV). Two patients (Cases 20 and 21) were believed to be poor surgical candidates because of diffuse severe left ventricular dysfunction or the absence of a discrete, resectable aneurysm. One patient (Case 23) died from intractable ventricular tachycardia before surgery could be performed. Two patients refused surgery. All of these patients were maintained on the antiarrhythmic regimen that made induction of ventricular tachycardia by programmed stimulation most difficult. Eleven of the 23 patients underwent surgery and will be described later.

TABLE III

Results of Holter Monitoring in Surgical Group

Case	Ineffective Regimens by Electrophysiologic Testing	Monitoring While VT Inducible	Postoperative	Postoperative Monitoring
8	All regimens	VT	VT not inducible	(1) 14 days postop → occasional VPDs (4 beat run) of nonsustained VT
9	All regimens	Recurrent VT	VT not inducible	(1) 1 month postop → 1–17 multiform VPDs/h (2) 2 month postop → $\overline{180}$ VPDs/h with bigeminy, pairs, triplets (3) 9 weeks postop → (procainamide, 500 mg q4h) → rare unifocal VPDs and couplets
10	Aprindine, 50 mg q12h Procainamide, 500 mg q4h	0 VPD/24 h 300–900 VPDs/h	VT not inducible	(1) 22 days postop → 500-200 VPDs/h, mean 59/h (uniform)
11	Baseline All regimens	Multiform, triplets, couplets VT	VT not inducible	(1) 13 days postop → 10–93 multiform VPDs/h (mean 43/h) with couplets, triplets* (2) 22 days postop → 20–50 multiple VPDs/h
12	Lidocaine, 4 mg/min IV Other regimens	0 VPD/24 h VT	VT not inducible	(1) 7 days postop → 0–78 multiple VPDs/h, 2 episodes unsustained VT
13	Quinidine, 400 mg q6h	VT	VT not inducible (on quinidine, 600 q6h for SVT)	(1) 13 days postop → (on quinidine, q6h) → 0–3 uniform VPD/h (mean 0.5/h)
14	Quinidine, 600 mg q6h Other regimens	Multiple runs of nonsustained VT, bigeminy Unavailable	VT not inducible	(1) 5 days postop → 20–748 VPD/h (mean 201/h), frequent couplets
15	Disopyramide, 15 mg q6h Other regimens	0–480 uniform VPDs/h VT VT	VT not inducible	(1) 4 days postop → 24–153 uniform VPDs/h (mean 168/h), couplets (2) 1 day postop (Norpace®, 150 mg q6h added) 72–385 unifocal VPDs/h (mean 64/h) (3) 1 yr postop (no medication) 10–150 VPDs/h
16	All regimens	VT	VT not inducible	(1) 12 days postop → bigeminy with exercise (2) 6 mo postop, 10–100 multiform VPDs/h
17	All regimens	0 VPDs/24 h on all regimens	VT not inducible	(1) 2 wk postop → multiform VPDs, couplets
18	Procainamide, 5 mg/min Quinidine, 300 mg q6h	0–2 VPDs, VT Occasional couplets	VT not inducible	(1) 2 wk Holter → 5–25 uniform VPDs/h (mean 16)

* Procainamide added by referring physician because of ventricular ectopic activity noted on Holter monitoring.

IV = intravenously; postop = postoperative; SVT = supraventricular tachycardia; VPDs = ventricular premature depolarizations; VT = ventricular tachycardia.

Fourteen (88 percent) of the 16 patients in whom medical therapy failed (Tables III and IV) underwent continuous electrocardiographic monitoring on a medical regimen that failed to prevent initiation of ventricular tachycardia by programmed stimulation, including the 11 patients subsequently undergoing surgery (Table III). Nine (67 percent) of the 14 continuously monitored patients manifested ventricular tachycardia (6 patients) or complex arrhythmias (3 patients) during at least one monitoring period while on an ineffective regimen. Two patients (Cases 18 and 20) had complete suppression of all ventricular ectopy on one of multiple ineffective regimens. In the remaining four patients noncomplex ventricular ectopic activity was observed during at least one monitoring period and ventricular ectopic activity was completely abolished by at least one antiarrhythmic regimen that proved ineffective in the electrophysiologic laboratory. Therefore, 6 (38 percent) of the 16 patients in whom medical treatment failed had almost complete suppression of ventricular ectopic activity on at least one medical regimen that did not prevent the initiation of sustained ventricular tachycardia.

Four of the five patients with unsuccessful medical therapy who did not undergo surgery (Table IV) had recurrent ventricular tachycardia in the follow-up period and continued to manifest complex ventricular ectopic activity on outpatient long-term electrocardiographic monitoring. One of these five patients (Case 22) demonstrated continued abolition of all ventricular arrhythmias while on a previously defined ineffective regimen. In this patient ventricular tachycardia could only be initiated by two ventricular extrastimuli during a basic drive cycle length of 300 ms on the previously defined ineffective regimen. There were no recurrences of ventricular tachycardia in 12 months of follow-up.

Patients undergoing surgical therapy after medical failure: Eleven of the 16 patients (69 percent) with unsuccessful medical therapy underwent surgery (Table III). Ten (90 percent) of the 11 underwent endocardial resection with (8 patients) or without (2 patients) aneurysmectomy in attempts to interrupt the tachycardia circuit. One patient (Case 14) underwent resection of scar tissue in the right ventricular outflow tract resulting from childhood repair of tetralogy of Fallot. In only one of these patients could sustained ventricular tachycardia be induced by programmed stimulation in the postoperative period.

All patients had at least one period of 24 hour electrocardiographic monitoring after postoperative electrophysiologic evaluation. Complex ventricular ectopic activity was seen in 10 of these 11 patients on at least one 24 hour recording. Runs of nonsustained ventricular tachycardia (three to five complexes) were noted in three patients (Cases 8, 11 and 12) but sustained ventricular tachycardia did not occur. Six additional patients (Cases 9, 11 and 14 to 17) manifested complex forms including couplets, triplets and multiform activity on at least one 24 hour recording. Only one patient (Case 18) demonstrated infrequent uniform ventricular ectopic activity with 5 to 25 uniform ventricular premature depolarizations/h (mean 16/h) during a 24 hour recording period. Patient 13 was treated with quinidine for atrial arrhythmias in the postoperative period. This patient had only infrequent uniform ventricular premature depolarizations (mean 0.5/h) during the 24 hour recording period. The mean frequency of ventricular premature depolarizations for this group was 112 ± 10/h, (mean ± standard error of the mean), excluding the single patient taking quinidine. Despite the frequency and complexity of ventricular ectopic activity universally noted in this group of patients, sustained

TABLE IV

Results of Holter Monitoring in Patients With Medical Failure (nonsurgical group)

Case	Ineffective Regimen	Monitoring on Regimen
19	Quinidine and disopyramide	(1) VT, syncope
	Phenytoin, 300 mg/d and propranolol, 40 q6h (regimen making VT most difficult to induce)	(1) 4 mo post study → frequent couplets, rare triplets
20	Procainamide, 750 mg q4h	(1) Rare uniform VPDs
	Procainamide, 1,250 mg q4h	(1) Isolated/24 h
	Procainamide, 1 g q4h + quinidine 300 q6h	(1) 0 VPDs/24 h
	Procainamide, 2 g q4h	(1) 0 VPDs/24 h
	Aprindine, 200 mg q6h	(1) 360–420 VPDs/h (2) Slow spontaneous VT (3) VT as outpatient 1 mo post study
21	Procainamide, 4 mg/min IV	(1) Bigeminy
	Quinidine, 600 mg q6h	(1) 2 triplets, rare uniform VPDs
22	Quinidine, 400 mg q6h	(1) 0 VPDs/24 h
	Disopyramide, 300 mg q6h + propranolol, 40 mg q6h	(1) 0 VPDs/24 h (2) 1 mo post study → 0 VPDs/24 h
23	Disopyramide, 200 mg q6h + aprindine, 150 mg q6h	(1) Couplets, rare uniform VPDs
	Disopyramide, 400 mg q6h + aprindine, 150 mg q6h	(1) VT → VF (recurrent) → died

SVT = supraventricular tachycardia; VPDs = ventricular premature depolarizations; VT = ventricular tachycardia.

ventricular tachycardia did not occur in the follow-up period of 2 to 29 months (mean 10.6) in any patient.

Discussion

Simple or complex ventricular activity as a marker for susceptibility to sustained ventricular tachycardia: The management of patients with recurrent sustained ventricular tachycardia often presents difficult problems despite the availability of several apparently effective antiarrhythmic agents. The therapeutic approach to this disorder has been based on the unproved assumption that simple or complex ventricular ectopic activity serves as a marker for the propensity of sustained ventricular tachycardia to develop. Therapeutic efficacy has therefore been assumed to correlate with suppression or elimination of ventricular ectopic activity on an empirically designed antiarrhythmic regimen. The results of our study suggest that ventricular ectopic activity may not serve as a marker for susceptibility to development of sustained ventricular tachycardia and therefore that the basic premise for empirically designed therapy may be invalid.

A recent report by Myerburg et al.[11] suggests that the presence or absence of complex ventricular ectopic activity on long-term electrocardiographic monitoring does not allow prediction of the patients likely to have recurrent out-of-hospital cardiac arrest. Although our patient population differs from that of their study, our data support a similar conclusion in patients with recurrent sustained ventricular tachycardia.

Programmed electric stimulation as a judge of therapeutic efficacy: Because empiric trials of antiarrhythmic agents must await the recurrence of ventricular tachycardia in order to define therapeutic failure, other methods have been sought for rapid and accurate assessment of success or failure. Programmed electric stimulation appears to be an effective and reliable technique for judging therapeutic efficacy. Several recent studies indicate that the induction of sustained ventricular tachycardia in the electrophysiologic laboratory correlates with its clinical occurrence[2–4] and that the inability to induce the tachycardia predicts its clinical absence.[1,3,6,9] Because the availability of these sophisticated electrophysiologic techniques is limited to a small number of large medical centers, we have sought to establish whether noninvasive evaluation utilizing long-term electrocardiographic monitoring would allow prediction of the success or failure of the therapeutic regimen or modality in question.

Holter electrocardiographic monitoring to predict therapeutic success or failure: Recent data have demonstrated the marked spontaneous variability of ventricular ectopic activity recorded by Holter monitoring.[12] Such variation limits the utility of this technique to assess drug efficacy and specifically to predict a sporadic event such as ventricular tachycardia. Thus we have prospectively evaluated the relation of spontaneous ventricular ectopic activity on Holter monitoring to the ability to induce ventricular tachycardia by programmed stimulation after therapeutic interventions. Although successful antiarrthythmic therapy was often associated with marked suppression of ventricular ectopic activity, patients in whom such therapy failed also frequently (38 percent) demonstrated suppression of ventricular activity. Moreover, successful surgical ablation of sustained ventricular tachycardia was almost invariably associated with the presence of complex ventricular arrhythmias on monitoring. Thus the presence or absence of arrhythmias on a Holter monitor recording could not predict the clinical results of therapy, although the clinical response did correlate with electrophysiologic testing.

Mechanisms of efficacy of antiarrhythmic agents and surgery in ventricular tachycardia: Two mechanisms for abolition of ventricular tachycardia are possible—eradication of the triggering mechanisms (that is, spontaneously occurring ventricular ectopic acitivity) or rendering the reentrant circuit incapable of sustaining reentry. In patients successfully treated with surgical interventions, the continued presence of simple and complex arrhythmias suggests that the mechanism for successful surgery was an alteration of the reentrant circuit. In contrast, in patients in whom ventricular tachycardia was abolished by antiarrhythmic agents, prevention of ventricular tachycardia was often associated with abolition of ventricular ectopic activity. However, the mechanism of successful antiarrhythmic therapy has not yet been determined. By definition, failure of programmed electric stimulation to reinitiate a tachycardia after administration of a certain drug was the basis for choosing subsequent antiarrhythmic therapy. Programmed electric stimulation only tests the ability of a potential reentrant circuit to sustain a reentrant tachycardia because the "triggers" are artificially induced. Because clinical recurrences of ventricular tachycardia are accurately predicted by electrophysiologic testing, alterations of the electrophysiologic properties of the reentrant circuit are the most likely mechanism of successful antiarrhythmic drug action. There was only one potential exception to this hypothesis; in one patient (Case 22) ventricular tachycardia was still inducible by programmed electric stimulation, yet no clinical ventricular tachycardia has recurred. However, the programmed electric stimulation required to initiate the tachycardia in this patient was unphysiologic (see previous discussion). Thus, it appears that alterations of the reentrant circuit are probably the method by which surgery or pharmacologic therapy, or both, successfully ablates long-term arrhythmias.

Clinical implications: Patients with complete absence of ventricular ectopic activity on a given drug regimen may still manifest recurrent ventricular tachycardia. In our experience the ventricular tachycardia of these patients can be initiated by programmed electric stimulation. Therefore, an a priori assessment of the efficacy of antiarrhythmic agents in preventing recurrent sustained ventricular tachycardia cannot be made solely from Holter monitoring of ventricular ectopic activity. Whether absence of ventricular ectopic activity in a patient in whom ventricular tachycardia *cannot* be induced by programmed electric stimulation

can serve as a marker for continued suppression of ventricular tachycardia is unknown. Further follow-up of such patients is required to assess whether the development of ventricular ectopic activity that is frequent or complex, or both, may indicate subtherapeutic drug levels due to noncompliance with therapy or a change in drug metabolism and portend a clinical episode of ventricular tachycardia.

Our results should be applied only to those patients with recurrent sustained ventricular tachycardia due to structural cardiac abnormalities as a result of ischemic heart disease or surgical repair of congenital heart disease. Patients with primary electric heart disease or arrhythmias temporally associated with transient myocardial ischemia may represent different patient populations with different electrophysiologic substrates.

Acknowledgment

We are grateful to John A. Kastor, MD, Chief of the Cardiovascular Section, Hospital of the University of Pennsylvania for his continued support and encouragement. We thank Gail Mitnick, RN and the laboratory technicians at the hospital of Pennsylvania for technical assistance and Marie Coscia for preparing the manuscript.

Study of Moxaprindine With Programmed Electrical Stimulation of the Heart in Patients With Reentrant Tachyarrhythmias

ANDRÉ WALEFFE, MD
LUC MARY-RABINE, MD
HENRI E. KULBERTUS, MD, FACC

Liège, Belgium

Moxaprindine, a new derivative of aprindine, possesses antiarrhythmic properties and is significantly less toxic than its parent compound on hematopoietic cells in culture. Its electrophysiologic effects were studied with programmed electric stimulation of the heart in 19 patients with recurrent episodes of reentrant tachyarrhythmias (atrioventricular nodal tachycardia, 8 cases; circus movement tachycardia involving an accessory pathway, 6 cases; ventricular tachycardia, 4 cases; ventricular tachycardia and atrioventricular nodal tachycardia, 1 case). Moxaprindine was perfused intravenously at a dose of 0.15 (10 cases) or 0.2 mg/kg per min (9 cases) during 15 minutes. Moxaprindine lengthened the conduction time along the His-Purkinje system as well as the refractory periods of right atrial and ventricular muscle. Depressing effects on the atrioventricular node were also seen, especially at the larger dose.

The effects of the drug on accessory pathways used in anterograde manner were measurable in three cases. Complete blockade along the bypass was seen in two and prolongation of the effective refractory period in the remaining one. After moxaprindine, five of six patients showed retrograde blockade along the accessory pathway, whereas the last subject had prolongation of the refractory period of the bypass used in a ventriculoatrial direction.

Perfused intravenously during episodes of tachycardia (atrioventricular nodal tachycardia, eight cases; circus movement tachycardia using an accessory pathway, six cases; ventricular tachycardia, three cases), the drug interrupted the rhythm disorder in all 17 instances. No tachycardia could be elicited after moxaprindine in 11 of the 19 patients. Among the six in whom sustained tachycardia could still be initiated, five had received the smaller dose.

It is concluded that moxaprindine is a potent antiarrhythmic agent whose long-term efficacy and toxicity in patients deserve further investigation.

Aprindine, an effective antiarrhythmic agent,[1–19] is currently available throughout most of Europe and is undergoing review for approval for use in the United States. Agranulocytosis[20] has recently been associated with chronic use of the drug. This complication is reversible if treatment is discontinued.[20]

Moxaprindine, a derivative of aprindine, which possesses antiarrhythmic properties in the dog, was recently submitted for initial clinical experimentation. The first results are promising.[21] This substance deserves attention because its inhibitory effects on hematopoietic cells in culture are less than those of aprindine (Collard E, Lambert M, Delespesse G, Stryckmans P, unpublished data). Our study was designed to evaluate the acute electrophysiologic effects of moxaprindine in 19 pa-

tients with paroxysmal arrhythmias easily reproducible by programmed stimulation of the heart.

Methods

Nineteen patients (10 male and 9 female) with reentrant tachyarrhythmias were studied. They ranged in age from 16 to 55 years (mean ± standard error of the mean 42.2 ± 12.9 years). They were referred to the laboratory for determination of optimal pharmacologic oral therapy by electrophysiologic testing. All patients had documented episodes of paroxysmal tachycardia (Table I). In 8 patients (Cases 1 to 4 and 10 to 13) the electrophysiologic investigation revealed the signs of reentrant intranodal tachycardia diagnosed according to previously described criteria.[24] Five patients (Cases 9 and 14 to 17) showed evidence of reentrant ventricular tachycardia. One of them (Case 14) also had intranodal tachycardia. Electrocardiographic evidence of the Wolff-Parkinson-White syndrome was present, at least intermittently, in 5 patients (Cases 5, 7, 8, 17 and 19) in whom circus movement tachycardia developed. In Patient 6, activity of the coronary sinus lead during tachycardia clearly preceded low right atrial activation, thus indicating the presence of a concealed left-sided bypass.[22–25] Previous drug treatment is outlined in Table II.

Electrophysiologic study: All patients gave informed consent. Cardioactive drugs were discontinued at least 72 hours before the procedure. Three catheters were passed through the right femoral vein using the Seldinger technique and positioned as previously described.[26] A fourth catheter was positioned either in the coronary sinus (when left-sided preexcitation was suspected) or in the right ventricular infundibulum (when paroxysmal ventricular tachycardia was diagnosed).

With the use of the single test stimulus method during atrial stimulation, the functional and effective refractory periods of the right atrium and the atrioventricular node were measured. Then, the right atrium was paced at increasing rates up to the development of second degree atrioventricular block or to a maximal pacing rate of 250 beats/min. Thereafter, with the single test stimulus method during right ventricular pacing, the pattern and effective refractory period of the ventriculoatrial conduction as well as the functional and effective refractory periods of the right ventricle were determined. Then, the right ventricle was paced at increasing rates either up to the occurrence of second degree ventriculoatrial block or up to a maximal pacing rate of 250 beats/min. For simplicity, only data derived at one cycle length will be presented.

Multiple premature stimuli and rapid pacing at different cycle lengths were used in an attempt to initiate reentrant tachycardia when single stimuli failed to do so. Definition of conduction intervals and refractory periods, as used here, has previously been described.[28]

The same measurements were repeated during the half hour after the perfusion of moxaprindine, using identical basic cycle length and test stimulus intervals. The drug was systematically administered during a sustained episode of arrhythmia except in Patient 16 in whom ventricular tachycardia was poorly tolerated and in Patient 11 in whom atrioventricular nodal tachycardia was never sustained before drug administration. In nine patients (Cases 1 to 9), moxaprindine was perfused at a dose of 0.2 mg/kg per min during 15 minutes (large dose) and in the others at a dose of 0.15 mg/kg per min during the same period (small dose).

TABLE I

Description of Study Patients

Case	Age (yr) & Sex	Type of Arrhythmias
	A. Large Dose	
1	55M	AVNT
2	51F	AVNT
3	34F	AVNT
4	55M	AVNT
5	47F	Intermittent right-sided accessory pathway
6	57F	Concealed left-sided accessory pathway
7	16M	WPW type A
8	21M	WPW type A
9	52M	Paroxysmal VT
	B. Small Dose	
10	41F	AVNT + flutter
11	31F	AVNT + flutter
12	46M	AVNT
13	34M	AVNT
14	51M	AVNT + paroxysmal VT
15	52M	Paroxysmal VT
16	46F	Paroxysmal VT
17	46M	Paroxysmal VT
18	49F	WPW type B
19	18F	WPW type B

AVNT = atrioventricular nodal tachycardia; VT = ventricular tachycardia; WPW = Wolff-Parkinson-White syndrome.
Large dose and small dose = 0.2 and 0.15 mg/kg per min of moxaprindine, respectively.

TABLE II

Previous Drug Treatment in 19 Patients

Case	Drugs Previously Used (alone or in combination)
1	Propranolol, 80 mg daily; verapamil, 120 mg daily
2	Quinidine bisulfate, 1,000 mg daily; disopyramide, 600 mg daily; aprindine, 100 mg daily
3	Disopyramide, 900 mg daily; deacetyl-lanatoside C, 0.50 mg daily;
4	Propranolol, 60 mg daily
5	Propranolol, 120 mg daily; verapamil, 80 mg daily; disopyramide, 600 mg daily
6	Amiodarone loading dose: 600 mg for 1 week; maintenance dose 150 mg daily 3 weeks per month
7	Quinidine bisulfate, 1,000 mg daily; disopyramide, 600 mg daily; propranolol, 120 mg daily
8	Disopyramide, 900 mg daily; verapamil, 160 mg daily
9	Tocainide, 800 mg daily; mexiletine, 400 mg daily
10	Propranolol, 40 mg daily; disopyramide, 600 mg daily; aprindine, 100 mg daily
11	Quinidine bisulfate, 1,000 mg daily; propranolol, 60 mg daily
12	Propranolol, 100 mg daily; deacetyl-lanatoside C, 0.25 mg daily
13	Verapamil, 120 mg daily; disopyramide, 300 mg daily
14	Propranolol, 120 mg daily; mexiletine, 800 mg daily; tocainide, 800 mg daily; aprindine, 200 mg daily; deacetyl-lanatoside, 0.75 mg daily; procainamide, 4,000 mg daily
15	Tocainide, 800 mg daily; mexiletine, 400 mg daily; aprindine, 200 mg daily
16	Aprindine, 100 mg daily
17	Mexiletine, 400 mg daily
18	Verapamil, 120 mg daily; propranolol, 60 mg daily
19	Quinidine bisulfate, 1000 mg daily; disopyramide, 600 mg daily; aprindine, 100 mg daily

No data on patient compliance are available; treatments were changed because of poor tolerance or unresponsiveness.

The position of the catheters remained unchanged throughout the procedure. All data obtained were recorded on tape (HP 8868 A recorder) and directly registered on an eight channel Elema recorder. Leads I, III, V_1, V_6, and intracavitary right atrial lead, the His bundle lead and left atrial lead, when available, were simultaneously recorded. Stimuli were delivered by a programmable stimulator (JSISU 2—Janssen, Beerse, Belgium).

Plasma levels of moxaprindine were determined by gas chromatography according to a method very similar to that used for the assay of aprindine.[27]

Results

Electrophysiologic Effects

For descriptive purposes, a distinction will be made between the patients who received a larger dose (0.2 mg/kg per min) or a smaller dose (0.15 mg/kg per min) of moxaprindine.

Effects of moxaprindine on basic electrophysiologic measurements: The mean spontaneous cycle length was unchanged after administration of the drug. The A-H interval increased (mean ± standard error of the mean) from 77 ± 22 to 114 ± 34 ms ($p < 0.001$) in the patients who received the large dose. It also increased in all but one patient receiving the small dose (from 89 ± 23 to 104 ± 25 ms). Because of the longer refractory period of the right atrium, the effective refractory period of the atrioventricular node could usually not be measured with accuracy. It could be assessed in three patients receiving the larger dose and lengthened in all three (Patient 1, +10 ms; Patient 4, +70 ms; Patient 8, +20 ms). The functional refractory period of the node, measurable in seven of nine subjects treated with 0.2 mg/kg per min, lengthened from 386 ± 54 to 439 ± 36 ms ($p < 0.05$). Inconsistent changes were observed at the dose of 0.15 mg/kg per min. The atrial pacing cycle length required to produce second degree atrioventricular block lengthened in all but one patient receiving the larger dose (mean variation for the whole group from 287 ± 44 to 400 ± 51 ms; $p < 0.001$); it also increased in duration in 8 of the 10 patients receiving the small dose (mean variation for the whole group from 312 ± 74 to 369 ± 67 ms; not significant).

The His-Purkinje conduction time (H-V interval) increased significantly from 41 ± 9 to 54 ± 10 ms ($p < 0.001$) in the smaller dose group and from 38 ± 6 to 62 ± 17 ms ($p < 0.001$) in the larger group.

After moxaprindine, the effective refractory period of the right bundle branch was reached in Patients 9 and 16, whereas the effective refractory period of the left bundle was reached in Patient 4.

All but one patient showed ventriculoatrial conduction during ventricular pacing. Retrograde con-

A = after drug administration; APC = atrial premature complex; at pac = atrial pacing; AVNT = atrioventricular nodal tachycardia; B = before drug administration; CMT = circus movement tachycardia; SR = sinus rhythm; sust= sustained; unsust = unsustained; VPC = ventricular premature complex; VT = ventricular tachycardia.

* Two different morphologies and cycle length.

duction occurred over the atrioventricular node in 14 patients. Moxaprindine abolished ventriculoatrial conduction in seven of these patients (four of the larger dose group; three of the smaller dose group) and considerably lengthened the effective refractory period of the ventriculoatrial conduction system in three who had received the smaller dose (increase greater than 70 ms in Case 10, 190 ms in Case 13 and 220 ms in Case 15). The results obtained in the five patients in whom ventriculoatrial conduction occurred along a bypass will be discussed in the following paragraph.

The effective refractory period of the right atrium increased from 220 ± 38 to 299 ± 34 ms ($p < 0.001$) after administration of the larger dose of moxaprindine, and from 211 ± 31 to 251 ± 43 ms ($p < 0.001$) after the smaller dose. Likewise, moxaprindine increased the effective refractory period of the right ventricle from 234 ± 19 to 274 ± 26 ms ($p < 0.001$) in the larger dose group and from 224 ± 24 to 257 ± 27 ms ($p < 0.001$) in the smaller dose group.

No attempt was made to measure the actual threshold for cardiac pacing. Nonetheless, it was noted that before drug administration, the pacing stimuli measured 0.8 ms in duration and 400 mA in intensity (±1.5 × threshold values). At small doses of moxaprindine, no change in stimulus characteristics was needed to obtain proper responses. At larger doses, it was necessary to use a stimulus of longer duration and higher intensity. The stimulus characteristics (±1.5 × threshold values) became 2 ms in duration and 900 mA in intensity.

Effects on accessory pathways: The effects of moxaprindine on the anterograde effective refractory period of accessory pathways could be assessed in Patients 7, 18 and 19. In Cases 7 and 19, preexcitation disappeared after drug administration; in Case 18, the effective refractory period of the accessory pathway increased from 280 to 320 ms. The effective refractory period of the bypass used in retrograde direction could be measured only in Patient 19; it lengthened from 300 to 480 ms. In the five other cases, a complete ventriculoatrial block occurred after drug administration along both the nodal axis and the accessory pathway.

Effects of Moxaprindine on Reentrant Tachycardias (Table III)

Atrioventricular nodal tachycardia (Fig. 1): Moxaprindine was injected during an episode of sustained atrioventricular nodal tachycardia in eight patients (four receiving the larger dose [Cases 1 to 4] and four receiving the smaller dose [Cases 10 and 12 to 14]). In every case, the tachycardia cycle length first increased considerably and then tachycardia stopped by blockade of either the fast retrograde pathway (Cases

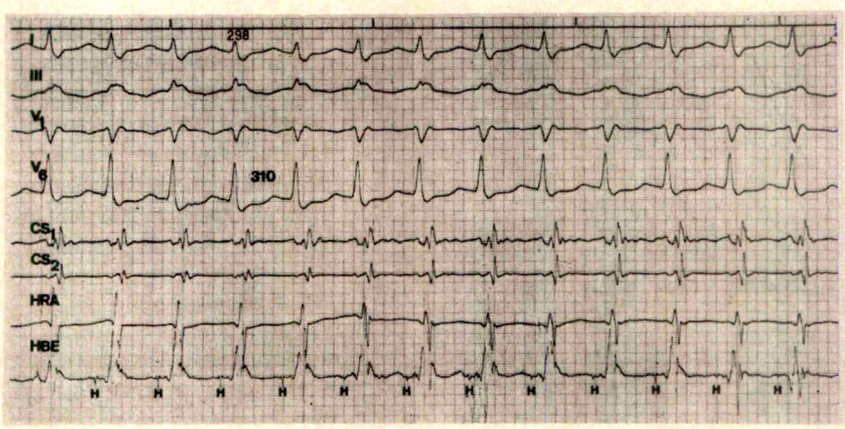

FIGURE 1A. Case 1. Atrioventricular nodal reentrant tachycardia with a cycle length of 310 ms (paper speed, 100 mm/s).

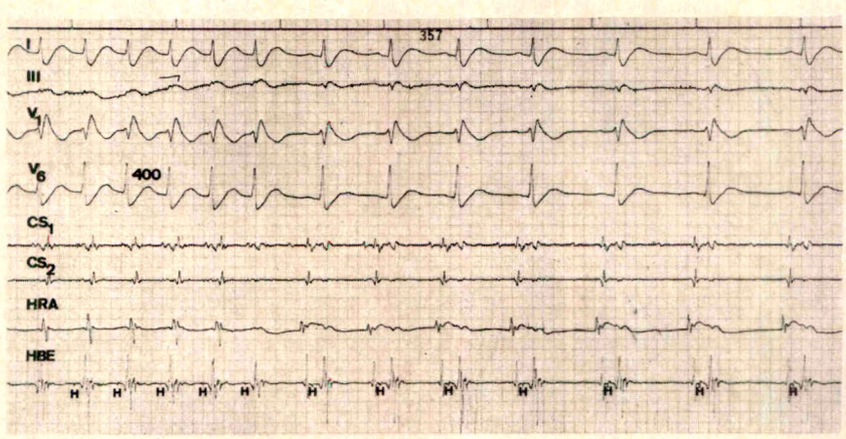

FIGURE 1B. Case 1. Four minutes after the start of moxaprindine perfusion (0.2 mg/kg per min), the tachycardia cycle length is prolonged (400 ms) and complete right bundle branch block develops. Sinus rhythm is restored by blockade along the fast retrograde pathway (paper speed, 50 mm/s). In this figure and in Figures 2 and 3, I, III, V and V_6, are standard electrocardiographic leads; CS and CS_2 are coronary sinus electrograms; HRA = high right atrial electrogram; and HBE = his bundle electrogram.

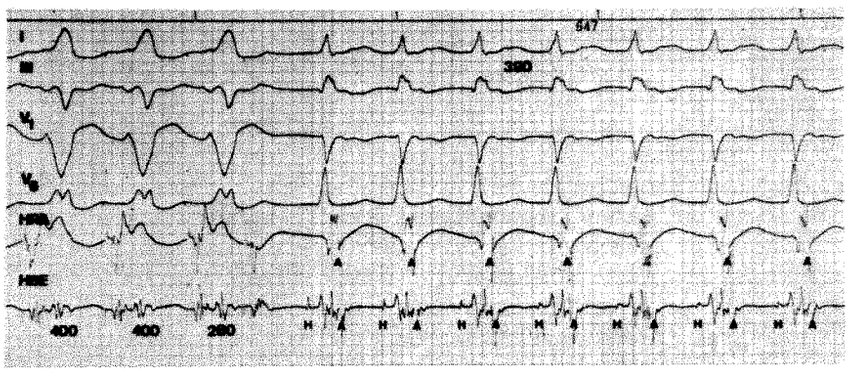

FIGURE 2A. Case 19. Patient with a right-sided accessory pathway. During right atrial pacing at a cycle length of 400 ms and with a coupling interval of 280 ms, the effective refractory period of the bypass is reached and circus movement tachycardia is initiated (paper speed, 100 mm/s).

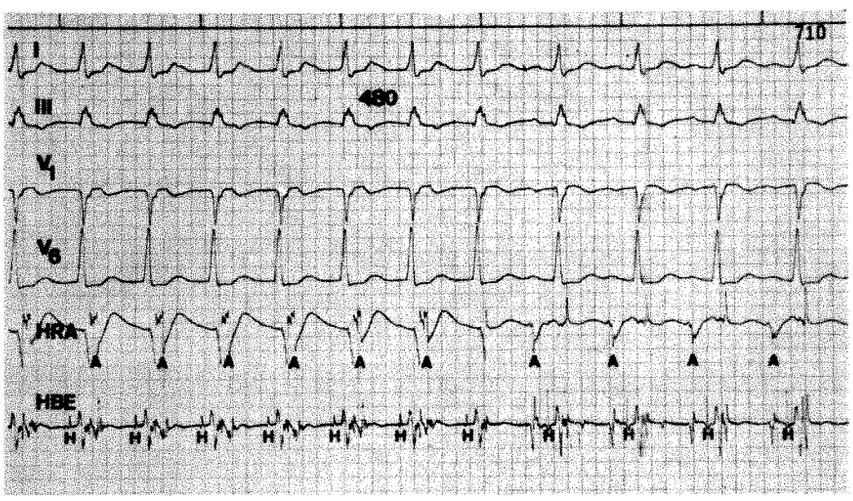

FIGURE 2B. Case 19. Six minutes after beginning the perfusion by moxaprindine (0.15 mg/kg per min), the tachycardia cycle length increases from 390 to 480 ms. Sinus rhythm is restored by blockade along the accessory pathway (paper speed, 50 mm/s).

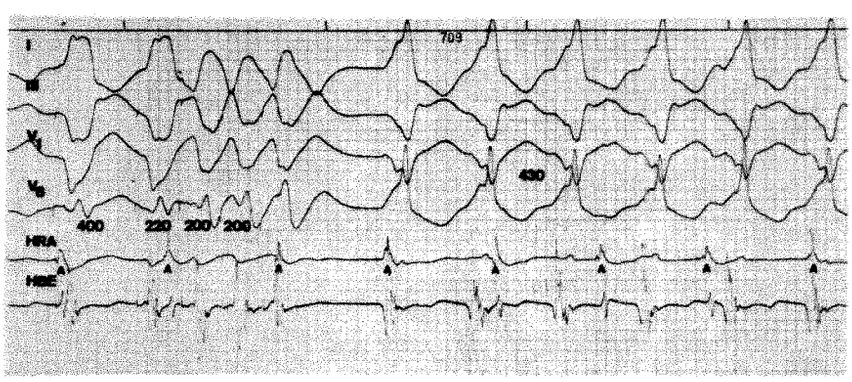

FIGURE 3A. Case 18. Initiation of ventricular tachycardia by introduction of 3 ventricular premature depolarizations during ventricular pacing at a cycle length of 400 ms (paper speed 100 mm/s).

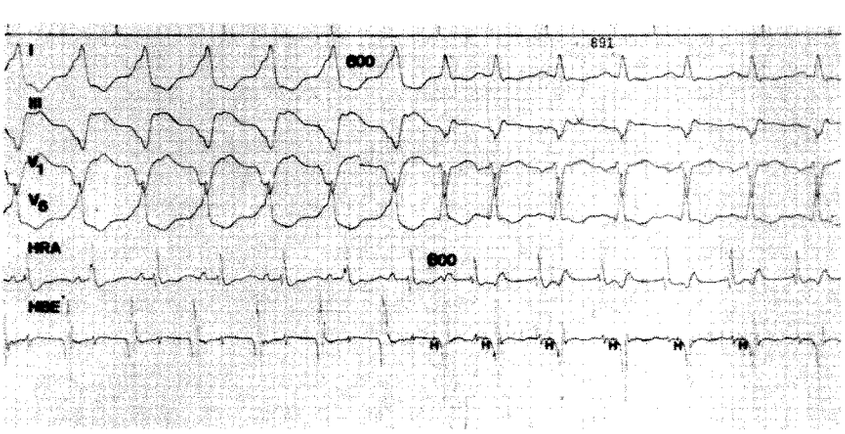

FIGURE 3B. Case 18. Eight minutes after initiation of moxaprindine perfusion (0.15 mg/kg per min), the tachycardia cycle length increases from 430 to 600 ms and sinus rhythm is restored by sinus capture (paper speed, 50 mm/s).

1, 3, 10 and 12 to 14) or the slow anterograde pathway (Case 2). In Patient 4, the tachycardia also stopped after increase of cycle length and the occurrence of two spontaneous atrial premature beats.

Atrioventricular nodal reentrant tachycardia could still be initiated after drug administration in only one patient (Case 3), but the tachycardia cycle length had considerably increased (from 270 to 370 ms). In Patient 11, only short episodes of atrioventricular nodal tachycardia could be elicited before drug administration. After injection of the drug, sustained atrioventricular nodal tachycardia was started by rapid atrial pacing.

Circus movement tachycardia incorporating an accessory pathway (Fig. 2): In six patients (four receiving the larger dose [Cases 5 to 8] and two receiving the smaller dose [Cases 18 and 19], moxaprindine injected during a sustained episode of circus movement tachycardia, after initially lengthening the cardiac cycle length, resulted in interruption of the rhythm disorder by retrograde blockade along the bypass. In four patients (Cases 5 to 8), no tachycardia could be initiated after drug administration. In one patient (Case 18), tachycardia could still be elicited but was not sustained after moxaprindine. Finally, in Case 19, moxaprindine widened the echo zone. Initiation of tachycardia became possible with one single atrial premature beat, whereas two ventricular premature beats or rapid ventricular pacing had been necessary during the control study. However, the cycle length had considerably increased from 400 to 450 ms) after moxaprindine.

Ventricular reentrant tachycardia (Fig. 3): In five patients (one receiving the larger dose [Case 9] and four receiving the smaller dose [Cases 14 to 17]), critically timed ventricular premature stimuli started episodes of ventricular reentrant tachycardia during the control period. In Patients 14 and 16, the arrhythmia was poorly tolerated from the start: Both required cardioversion. In the three other patients, the drug was perfused during an episode of sustained, well tolerated ventricular tachycardia. It interrupted the rhythm disorder in all three.

After drug administration, no sustained ventricular tachycardia could be elicited in Cases 9 and 15; in the three others (Cases 14, 16 and 17), ventricular tachycardia could still be started, but the cycle length of the tachycardia had increased, allowing a better tolerance.

Drug Plasma Levels

The peak drug plasma level measured at the end of injection ranged from 1.81 to 7.40 γ/ml in the larger dose group and from 0.80 to 4.87 γ/ml in the smaller dose group. The mean drug plasma concentrations measured at the end of injection as well as 15, 30 and 45 minutes later are indicated in Figure 4. There was no difference between plasma levels obtained in a subject who showed no response to the drug compared with levels in patients who did show a drug response.

Side effects: During this acute study, no side effects were observed. Intravascular monitoring of blood pressure was not performed, but blood pressure was repeatedly measured by sphygmomanometer. No significant pressure change was noted.

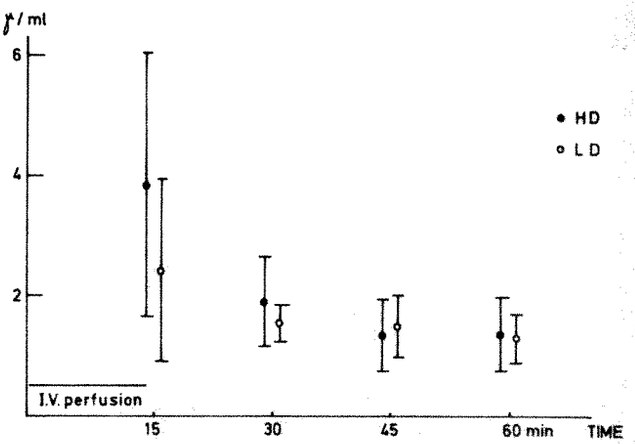

FIGURE 4. Mean plasma levels of moxaprindine (γ/ml) observed after intravenous (IV) perfusion of the drug at the dose of 0.2 mg/kg per min during 15 minutes (5 cases, larger dose) or 0.15 mg/kg per min during 15 minutes (10 cases, smaller dose).

Discussion

Since 1972, several reports[1–19] have repeatedly stressed the value of aprindine for short- and long-term treatment of refractory supraventricular as well as ventricular arrhythmias.[1–19] Chronic use of the drug frequently produces tolerable side effects such as tremor. Unfortunately, recent reports indicate that agranulocytosis[18–20] and cholestatic jaundice[18] are also associated with prolonged aprindine administration. These observations prompted studies aimed at developing molecules derived from aprindine that would maintain its antiarrhythmic properties but would be less toxic. Initial investigations[21,22] have shown that moxaprindine is very efficient in its effect on ventricular ectopic activity both at rest and during exercise.[21] Pharmacologic studies using cultured bone marrow cells indicate that moxaprindine is significantly less toxic on hematopoietic cells than aprindine itself (Collard E, Lambert M, Delespesse G, Stryckmans P, unpublished data). Our investigation was designed to evaluate the acute electrophysiologic effects of moxaprindine in patients with paroxysmal tachycardia easily reproduced in the laboratory by programmed electric stimulation of the heart.

Electrophysiologic effects of moxaprindine: Moxaprindine lengthened the conduction time along the His-Purkinje system and prolonged the refractory periods of the right atrial and ventricular muscle. The drug also produced definite depressing effects on the atrioventricular node. Altogether, the results obtained with moxaprindine were quite comparable with those reported with aprindine itself.[14,15,18] The observed changes were also of the same order of magnitude.

Moxaprindine produced a marked effect on accessory pathways used in an anterograde direction. This

effect was seen even in one patient (Case 7) who had a short refractory period of the accessory pathway (250 ms) and in whom anterograde block developed along the bypass. The effects were even more conspicuous in a retrograde direction; indeed, in five of six cases, complete ventriculoatrial block along the accessory pathway followed the injection of moxaprindine. In the remaining patient, the refractory period of the bypass increased by 180 ms. These results deserve attention because the drug also suppressed ventriculoatrial conduction in half of the patients who, during the control period, showed ventriculoatrial conduction along the His nodal axis. This profound depressive effect on the transmission of impulses from the ventricular to the atrial level may be of greatest clinical interest to prevent ventricular ectopic complexes from initiating tachycardias incorporating the normal or an accessory atrioventricular pathway in the reentrant circuit.

Effects on tachycardia: The effects of moxaprindine on tachycardias were also remarkable. Perfused intravenously during episodes of tachycardia in 17 patients, it interrupted the rhythm disorder in all instances. In addition, no tachycardia could be elicited after drug administration in 11 of 19 patients. In three of the remaining patients tachycardia could be triggered more easily after moxaprindine. This paradoxic effect may at times be seen with almost all antiarrhythmic agents. In Case 19, initiation was most probably facilitated by a slowing of transmission along the atrioventricular nodal His axis.[26,28–33] A similar mechanism, consisting of delayed conduction along a portion of the reentrant circuit, thus permitting another portion to be reached after the end of its refractory period, might similarly account for the paradoxic facilitation seen in Case 17. Finally, another form of paradoxic effect was observed in Patient 11, in whom sustained episodes of atrioventricular nodal tachycardia could be elicited only after drug administration. Some vagolytic effect, corresponding to what is frequently seen with antiarrhythmic agents injected intravenously and illustrated in this case by shortening of the functional refractory period of the node and of the basic cycle length inducing second degree atrioventricular block, might explain the development of sustained atrioventricular nodal tachycardia after drug perfusion.

Studies after the acute administration of a drug have obvious limitations. Nonetheless, recent reports[36–41] underline that favorable results obtained by intravenous perfusion of a drug can be extrapolated to long-term oral use.[34–39] Therefore, moxaprindine appears to share the electrophysiologic properties of aprindine. Our findings, like those of others,[21] indicate that it is a very potent antiarrhythmic agent. The slowing of conduction along the His-Purkinje system stresses the need for careful monitoring of the P-R interval when moxaprindine is used in patients with intraventricular conduction defects. However, in a recent report[42] dealing with aprindine used intravenously, several patients had severely impaired conduction but no block occurred after the drug.

Chronic studies consisting of a meticulous scrutiny of all possible side effects are now required to establish the safety of moxaprindine in long-term oral treatment. The need for new molecules efficient for therapy of refractory arrhythmias amply justifies such studies.

Acknowledgment

We are thankful to Christiaens, Société Anonyme, Belgium, who provided the drug and performed the measurements of blood levels of moxaprindine, and to Betty Vervier, Flore Courtois and Simone Smeets for secretarial and technical assistance.

Sustained Hemodynamic Effects Without Tolerance During Long-Term Isosorbide Dinitrate Treatment of Chronic Left Ventricular Failure

JOSEPH A. FRANCIOSA, MD, FACC*
JAY N. COHN, MD, FACC

Minneapolis, Minnesota

Vasodilators produce beneficial acute hemodynamic effects in patients with congestive heart failure and are employed in long-term management. Tolerance has developed with respect to the hemodynamic effects of prazosin in heart failure, whereas the long-term effects of nitrates are little known. Hemodynamic values were measured in 19 patients with chronic left heart failure before and 90 minutes after oral administration of 40 mg of isosorbide dinitrate. Patients were then randomly assigned in double-blind fashion to receive isosorbide dinitrate (9 patients) or placebo (10 patients), 40 mg four times daily, for 3 months, after which hemodynamic values were measured again before and 90 minutes after administration of the test drug. Both groups of patients responded similarly with a significant decrease in pulmonary wedge and systemic arterial pressures after the first dose of nitrate. After 3 months of isosorbide dinitrate treatment the pulmonary wedge pressure was significantly below control values (-2.5 ± 0.9 mm Hg [mean ± standard error of the mean]; $p < 0.02$) and decreased another 5.4 ± 1.5 mm Hg after a dose of isosorbide dinitrate ($p < 0.01$). In the placebo group, pulmonary wedge pressure at 3 months was unchanged from control values (-1.2 ± 2.1 mm Hg) and failed to change significantly after another dose. In the nitrate-treated group a dose of isosorbide dinitrate at 3 months also reduced mean systemic arterial pressure (-9.3 ± 2.0 mm Hg; $p < 0.01$) and systemic vascular resistance (-7.8 ± 3.7 units; $p < 0.05$). Thus, long-term administration of isosorbide dinitrate is associated with sustained hemodynamic effects and hemodynamic responsiveness in patients with congestive heart failure.

The use of vasodilators to reduce left ventricular outflow resistance has gained widespread interest as a method of managing congestive heart failure. Several studies[1–4] have demonstrated marked hemodynamic improvement early after their administration to hospitalized patients with severe or refractory heart failure. Thus, their use has been logically extended to long-term treatment of congestive heart failure.

The most widely used agents for long-term therapy have been nitrates, hydralazine and prazosin.[5–11] The development of drug tolerance, as measured by lessening of hemodynamic effects, has been reported[12] during administration of prazosin to patients with congestive heart failure. Hydralazine is a well known vasodilator that has not been associated with development of significant tolerance in hypertensive patients; preliminary studies[13] in patients with congestive heart failure have also shown continued responsiveness to hydralazine during long-term administration. The long-term hemodynamic effects of nitrates in

congestive heart failure have not been extensively studied, although the possibility of tolerance to these agents developing during their use in treatment of angina pectoris has long been suggested.[14–16] Recent studies[17] of long-term treatment of angina with isosorbide dinitrate showed that neither tolerance to this drug nor a cross-tolerance to nitroglycerin developed. However, other studies,[16–19] have suggested some tolerance developing with respect to the venodilating action of nitrates, which may be their most important effect in congestive heart failure. The present study was therefore designed to evaluate the long-term hemodynamic effects of nitrates in patients with congestive heart failure to determine whether the initial improvement is maintained over time and if acute responsiveness persists.

Methods

Patients: Twenty-four patients with chronic congestive heart failure present for at least 3 months were selected for study. The diagnosis of congestive heart failure was established on clinical grounds by the presence of a ventricular gallop sound, jugular venous distension, pulmonary rales and otherwise unexplained peripheral edema. Radiologic evidence of pulmonary vascular congestion or cardiomegaly was also present. The cause of congestive heart failure was either ischemic or primary cardiomyopathy. The diagnosis of ischemic cardiomyopathy was based on a previous, documented acute myocardial infarction or on coronary angiographic demonstration of significant coronary arterial occlusive disease. The diagnosis of primary myocardial disease was established when no other cause of congestive heart failure could be demonstrated. Patients were excluded if they had had a myocardial infarction within the past 4 months or had a history of angina pectoris requiring nitrate administration, primary valvular heart disease or primary lung disease. In patients meeting the foregoing criteria, written informed consent was obtained before their entry into the protocol, which had been reviewed and approved by the Subcommittee on Human Studies of this institution.

Hemodynamic measurements: Patients were brought to the laboratory where Swan-Ganz catheterization was performed for measurement of pulmonary arterial pressures; heart rate and rhythm were monitored from a standard electrocardiogram and blood pressure was measured with the standard cuff technique. Cardiac output was measured noninvasively by the carbon dioxide rebreathing method, an indirect Fick procedure that we have previously described and validated in patients with congestive heart failure.[20,21] Pulmonary wedge pressure was taken as the occluded pulmonary arterial pressure or the pulmonary arterial diastolic pressure. In any given patient the same pressure measure was used throughout all studies because these pressures were not interchanged. Pressures were measured using a Bell and Howell transducer positioned at the mid axillary line with the patient supine. Pressure tracings were displayed on a Mechanics for Electronics direct writing recorder.

Protocol: On day 1 of the study, after control hemodynamic measurements were obtained with the patients supine and at rest, isosorbide dinitrate, 40 mg orally , was administered. Measurements were repeated 90 minutes later. All patients received active drug on day 1 to assure that all responded to this agent. Upon completion of these studies on day 1 patients were then randomly assigned in double-blind fashion to receive isosorbide dinitrate, 40 mg (two tablets) four times daily, or identical-appearing placebo tablets, two tablets four times daily. Patients were maintained on this regimen for 3 months and were seen at monthly intervals in the clinic. During the 3 month follow-up period the dosages of digitalis and the test drug were kept constant, whereas diuretic dosage was adjusted as needed. At the end of 3 months patients were instructed to withhold their diuretic drugs for 24 hours before reporting to the laboratory early in the morning. On their arrival in the laboratory all medications, except for the test drug and diuretic agent, were given, after which Swan-Ganz catheterization was performed again and all measurements were repeated as on day 1. The patients were then given their coded test drug and measurements were repeated 90 minutes later.

Randomization and follow-up study: Of the initial group of 24 patients, 12 were assigned to each treatment regimen. Three of those assigned to receive isosorbide dinitrate failed to complete the 3 month follow-up study. One patient with primary myocardial disease, who had been doing well, died suddenly after 2 months. One patient refused to continue in the study because of persistent symptoms of congestive heart failure and one other patient had a nonfatal stroke after 2 months. Of the 12 patients assigned to receive placebo, two failed to complete the 3 month trial. One patient with ischemic heart disease died suddenly at home 10 days after randomization and one other patient refused to continue in the study because of persistent symptoms of heart failure after 6 weeks. Thus, of this initial population, 19 completed the trial; 10 were assigned to the placebo and 9 to the isosorbide dinitrate group.

*Measured before drug administration, after 3 months of treatment (compared with control data of Table II).
NS = not significant; p = probability; SEM = standard error of the mean.

The remainder of this report will deal primarily with the hemodynamic responses in these 19 patients.

Statistics: Calculated variables included mean arterial pressure, which was calculated as the diastolic arterial pressure plus one third of the pulse pressure. Systemic vascular resistance was calculated as mean arterial pressure (in mm Hg) divided by cardiac output (in liters/min) and expressed in units. Statistical analysis was performed employing Student's t test.

Results

Clinical groups: The clinical characteristics of patients before random assignment to receive isosorbide dinitrate or placebo are shown in Table I. There were no significant differences between the groups in age, severity of congestive heart failure, cardiothoracic ratio or etiology of heart disease. All patients were receiving prior treatment with digitalis and diuretic drugs. Among those patients ultimately randomized to isosorbide dinitrate therapy, two had previously been taking vasodilators for heart failure, whereas in the placebo group three patients had been receiving prior vasodilator therapy. A systolic murmur consistent with relative mitral insufficiency was present in six of the placebo-treated patients and in five of the nitrate-treated group.

Hemodynamic responses to the first dose of isosorbide dinitrate in all patients (Table II): Pulmonary wedge pressure and mean arterial pressure decreased significantly and similarly in both patient groups. Heart rate, cardiac index and systemic vascular resistance were not significantly different after nitrate administration. Although cardiac index failed to increase significantly in the total group, some of these patients had a control index greater than 2.5 liters/min per m^2; in 10 of the 13 patients with a control index below 2.5, cardiac index increased as expected.[19] The acute hemodynamic responses thus demonstrated that both groups of patients responded similarly to nitrate administration.

Hemodynamic changes present after 3 months of treatment with isosorbide dinitrate or placebo compared with prerandomization control values (Table III): These measurements were made early in the morning before administration of the test drug, and the last previous dose of test drug was given at bedtime the night before. Thus, the measurements reported represent observations made at least 8 hours from the last previous dose of medication. This time period exceeds the known duration of action of single doses of isosorbide dinitrate.[18] Despite these considerations pulmonary capillary wedge pressure was still significantly, although only mildly, reduced in those patients who had been taking isosorbide dinitrate for 3 months. The pulmonary wedge pressure in the placebo-treated patients was not significantly different at 3 months from the control value. The mean arterial blood pressure in both groups was significantly higher at 3 months. All other hemodynamic variables were unchanged. Thus, the nitrate-treated group continued to show reduced pulmonary wedge pressure after 3 months of therapy, whereas no changes could be demonstrated in the placebo-treated group.

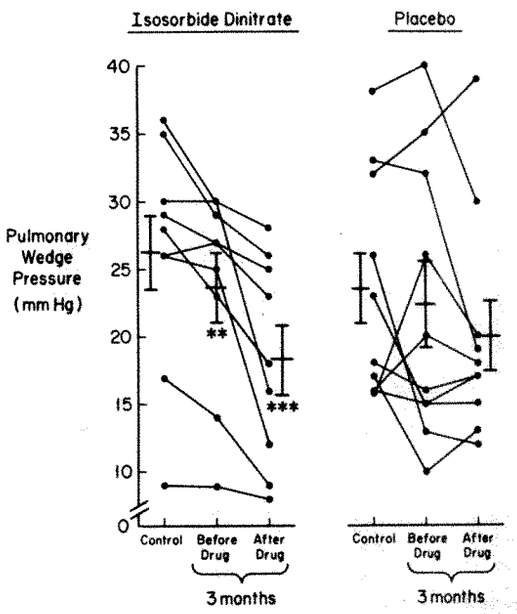

FIGURE 1. Effect of long-term administration of isosorbide dinitrate on pulmonary wedge pressure in patients with congestive heart failure. **Heavy bars** represent mean and standard error of the mean. ** = $p < 0.02$ compared with control value; *** = $p < 0.01$ compared with value before drug administration.

A new dose of test drug given at 3 months produced a significant reduction in pulmonary wedge pressure in the patients receiving isosorbide dinitrate (Fig. 1). In these patients a single dose of nitrate after 3 months of treatment still reduced wedge pressure by 5.4 ± 1.5 mm Hg ($p < 0.01$). In the placebo-treated group there was an insignificant change in wedge pressure after administration of placebo at 3 months. Mean arterial pressure also decreased significantly after nitrate administration at 3 months by 9.3 ± 2.0 mm Hg ($p < 0.01$) (Fig. 2); after placebo at 3 months there was no change in the mean arterial pressure. Cardiac index also rose slightly but not significantly after nitrate administration at 3 months, whereas it was unchanged by placebo. Systemic vascular resistance decreased significantly after nitrate administration at 3 months, but not after placebo (Fig. 2). Thus, single doses of nitrate still produced significant hemodynamic effects in patients who had taken nitrates for 3 months.

Role of diuretic drugs: Because the administration of diuretic drugs was adjusted during the 3 month follow-up period, it is possible that changes in diuretic dosage could have affected the pulmonary wedge pressure. Therefore data were analyzed separately for those patients whose diuretic dosage was changed. In the group treated with isosorbide dinitrate, the diuretic dosage was increased in four patients during the 3 month period and unchanged in the other five. In those whose diuretic dosage was increased, pulmonary wedge pressure after 3 months of treatment was reduced by 2.5 ± 1.3 mm Hg, which was not significantly different from the −5.3 ± 1.9 mm Hg change in those patients whose diuretic dosage was unchanged. Likewise a single dose of nitrate at that point reduced pulmonary wedge

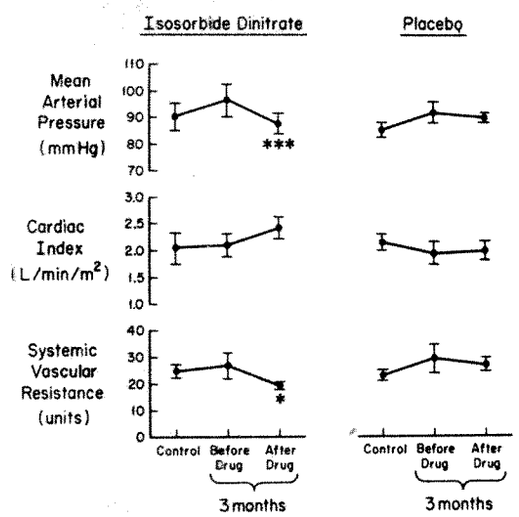

FIGURE 2. Hemodynamic effects of long-term administration of isosorbide dinitrate in patients with congestive heart failure. Mean values and standard error of the mean are plotted. * = $p < 0.05$ and *** = $p < 0.001$, both compared with value before drug administration.

pressure by 2.6 ± 1.4 mm Hg in the group whose diuretic dosage was increased and by 5.4 ± 3.1 mm Hg in the group whose dosage was kept constant. This difference was also not significant. Similarly, in the placebo-treated group the changes in pulmonary wedge pressure at 3 months before and after drug administration were not significantly different in patients whose diuretic dosage was increased as compared with those whose diuretic dosage was kept constant. Thus, changes in diuretic dosage do not appear to explain the reduction in pulmonary wedge pressure observed after 3 months of nitrate therapy.

Morbidity and mortality: Although hemodynamic improvement and responsiveness to medication were maintained after 3 months of nitrate therapy, nitrate treatment had no significant effects on morbidity or mortality in this group of patients (Table IV). The number of deaths and morbid events was the same in the two groups of patients during the 3 month follow-up period. It should be noted that the data of Table IV include those from the five patients who did not complete the 3 month trial because of significant morbidity. If these patients are excluded, there were still no differences among the 19 patients who completed the 3 month trial: five morbid events occurred in each of the treatment groups. Thus, hemodynamic improvement in this group of patients was not associated with decreased morbidity.

TABLE IV

Effects of Long-Term Isosorbide Dinitrate Administration on Morbidity in Patients With Congestive Heart Failure

	Isosorbide Dinitrate	Placebo

Average follow-up (wk)	11.3	10.7
Total patient-weeks of treatment	136	128
Morbid events		
Death	1	1
Hospitalization		
More severe heart failure	3	2
Cerebrovascular accident	1	0
Increased diuretic requirement	3	3
Symptomatic worsening	0	1
Total events	8	7

Discussion

Several vasodilators, including the nitrates, improve hemodynamics in patients with congestive heart failure by decreasing left ventricular and pulmonary arterial pressures and by raising cardiac output.[4,19] The acute effects of vasodilators are often so striking that this form of therapy is frequently used in the hospital to treat patients with severe or refractory congestive heart failure.[22–29] The frequent success of such short-term vasodilator therapy has logically led to an interest in its use in the long-term management of chronic congestive heart failure.[5–11] Whether the immediate hemodynamic effects of vasodilator drugs can be sustained over the long term has received some attention in recent years. The alpha blocking vasodilator agent prazosin produces the characteristic vasodilator-induced hemodynamic improvement in patients with congestive heart failure.[25] However, it has been shown that the hemodynamic effects at rest of this drug are rapidly attenuated and that tolerance to the drug may develop as early as the third or fourth dose.[12] Hydralazine is not subject to development of tolerance very readily when used to treat hypertension and preliminary data in patients with congestive heart failure suggest that an increased cardiac output in this situation is maintained.[13] There is little information concerning the long-term hemodynamic effects of nitrates in patients with congestive heart failure.

Development of tolerance to nitrates: The possibility that tolerance may develop to nitrates during their long-term use was noted as early as the 19th century[14] and continues to be reported.[15–17] There is clinical evidence that some form of tolerance develops during nitrate administration because the frequently observed vascular headaches that occur after nitrate administration often disappear after continued use of the drug.[26] Munitions workers, who are chronically exposed to nitrates in their work environment, become tolerant to these same vascular headaches. If they are absent from work for a sufficient period of time and then reexposed to nitrates, they may experience striking symptoms, varying from severe vascular headaches to episodes of angina and even sudden death.[27] The problem of the development of tolerance to nitrates involves the development of not only tolerance to a given nitrate but also cross-tolerance among nitrates, especially between long-acting nitrates and nitroglycerin. Schelling and Lasagna[15] reported development of cross-tolerance to sublingual nitroglycerin after 1 week of administration of pentaerythrol tetranitrate in normal subjects. In their study the decrease in systolic blood pressure that occurred after administration of

sublingual nitroglycerin was significantly attenuated after treatment with the long-acting nitrate.

In an attempt to explore the mechanism of this development of tolerance, Needleman and Johnson,[28] using an in vitro model, showed that the vasodilatory responses of vascular strips exposed to nitroglycerin were attenuated in the presence of nitrates. They suggested that the tolerance was neither the result of increased biotransformation of organic nitrates nor the result of increased sympathetic compensatory responses. They suggested that biochemical alterations of the nitrate receptor site in vascular smooth muscle were present so that the critical sulfhydryl group in the receptor was transformed into a disulfide with much lower affinity for nitrates. Responsiveness of the in vitro model could be restored by reduction of the disulfide. These same authors also showed that in vivo cross-tolerance could be developed between the organic nitrates and nitroglycerin. Vascular strips from animals treated with organic nitrates were less responsive to nitroglycerin-mediated vasodilation. Of the various nitrates they tested, isosorbide dinitrate was the least effective in producing cross-tolerance.[28]

In an effort to study nitrate effects more objectively in man, Zelis and Mason[16] measured changes in blood flow and venous capacitance in the calf after nitroglycerin administration before and after long-term therapy with large dose isosorbide dinitrate. They demonstrated continued increases in blood flow and decreases in systemic vascular resistance during long-term nitrate therapy. However, venous capacitance, which increased significantly after nitroglycerin administration prior to isosorbide dinitrate therapy, failed to change when nitroglycerin was given after chronic treatment with isosorbide dinitrate. They concluded that long-term administration of isosorbide dinitrate does induce cross-tolerance to nitroglycerin's venodilating effect, but not to its arterial dilating action. In a recent study,[17] nitrate cross-tolerance and self-tolerance during long-term large-dose isosorbide dinitrate administration did not develop in a group of patients with angina pectoris; their exercise capacity improved after nitroglycerin administration both before and after long-term isosorbide dinitrate therapy. Thus, it appears that the question of nitrate tolerance is not completely resolved. Some form of tolerance is manifested clinically by the disappearance of headache and perhaps by the attenuation of certain hemodynamic effects.

Pulmonary capillary wedge versus arterial pressure as indicator of nitrate responsiveness: In our study in patients with congestive heart failure we utilized changes in pulmonary capillary wedge pressure as an indicator of responsiveness to nitrates. Acute responsiveness to isosorbide dinitrate administration persisted unaltered after 3 months of treatment with large dose isosorbide dinitrate, which also still produced a decrease in arterial blood pressure after 3 months of treatment. Thus, tolerance to nitrates as shown by hemodynamic effects at rest does not develop during prolonged treatment in patients with congestive heart failure. We observed a greater increase in cardiac index and greater decrease in systemic vascular resistance after acute nitrate administration after 3 months of treatment. This phenomenon is consistent with the previous observation[16] that the effects of nitrates on veins may be mitigated during long-term therapy. If this occurred in our study the reduced venodilating effect could have permitted a greater rise in cardiac output. A decrease in pulmonary wedge pressure need not necessarily reflect a venodilating action, but could also be due to a decrease in left ventricular outflow resistance with concomitant reductions in end-systolic and end-diastolic volumes. A direct effect of the drug on pulmonary vessels is also possible. Furthermore, our data, like those of Zelis and Mason,[16] point out the importance of selecting a proper index of drug effect if one is to study tolerance. Measurement of arterial pressure may not be the most sensitive index because it is well known that regulation of systemic arterial pressure is extremely complex and various compensatory mechanisms are invoked in response to a sudden decrease in blood pressure.

Continued responsiveness to nitrates versus clinical improvement: Despite demonstrating continued responsiveness to the nitrates, we were unable to show any effect of this therapy on morbidity in these patients with heart failure. This finding is in contrast to our previous experience,[5] in which a reduction in morbid events was found in patients with heart failure who were taking isosorbide dinitrate. However, the earlier study was a crossover trial, which involved fewer patients and in which the treatment period was only 8 weeks. The patients entered in that series were generally more severely ill. Of course, neither the previous study nor the present one should be considered conclusive given the small numbers of patients and relatively short follow-up periods in both trials. We also noted in that earlier series an increase in exercise tolerance during prolonged nitrate therapy. In the present study exercise capacity was measured in 16 patients as part of another study to be reported in detail elsewhere. We have preliminarily noted increased exercise tolerance after 3 months of therapy with isosorbide dinitrate in these patients.[29]

Clinical implications: Our study shows that the hemodynamic effects of large dose isosorbide dinitrate are sustained and that tolerance to the drug does not develop during long-term administration in patients with congestive heart failure. Because similar findings have been preliminarily reported for hydralazine, whereas prazosin has been associated with the development of drug tolerance,[9,12] it is possible that the combination of hydralazine plus nitrate may be preferable to prazosin in the long-term therapy of congestive heart failure. However, the importance of tolerance should not be exaggerated since the assessment of efficacy of these drugs has relied almost exclusively on measurement of hemodynamics at rest. It has recently been shown[30] that the hemodynamic effects of prazosin are present during exercise, whereas apparent tolerance to the drug with respect to its hemodynamic effects could be demonstrated in the same patients at rest.

Furthermore the long-term administration of prazosin does improve cardiac performance, clinical status and exercise capacity in patients with heart failure.[10,11] Our study further demonstrates that the persistent hemodynamic efficacy of vasodilator drugs in heart failure should not be overemphasized since it may not correlate with clinical improvement in these patients. Indeed, it is not clearly established that either immediate responsiveness to vasodilators or sustained hemodynamic effects of vasodilators predict clinical improvement in patients with congestive heart failure. This has important implications for future studies of vasodilators in chronic heart failure, which should emphasize effects on morbidity and mortality in large scale long-term controlled trials.

Acknowledgment

We thank Susan Ziesche, RN and Mary Wilen for their valuable technical assistance and Margaret Chelmo for her skillful preparation of the manuscript. We also are grateful to Clarence Denton, MD of Ives Laboratories, Inc., New York, New York, for generously providing coded supplies of isosorbide dinitrate and placebo.

To evaluate the doses of hydralazine needed to obtain significant hemodynamic responses in severe chronic refractory heart failure, 45 consecutive patients received incremental doses of the drug during invasive hemodynamic monitoring. Twenty-six patients (group A) responded to the oral administration of single doses of 100 mg of hydralazine, whereas 19 patients (42 percent) (group B) did not. Of the patients in group B, 14 responded to 150 to 300 mg orally as a single dose, 3 patients required a single dose of 600 or 800 mg orally and 2 patients responded only to intravenous administration of the drug.

In spite of the different dosage requirements of hydralazine, the hemodynamic responses to effective doses were similar in the two groups. The control etiologic, pathophysiologic and hemodynamic variables were similar in both groups, except that patients in group B had higher control values for mean right atrial pressure (14.0 ± 1.5 versus 9.2 ± 1.3 mm Hg; $p < 0.025$) and left ventricular filing pressure (25.2 ± 1.2 versus 21.7 ± 1.0 mm Hg; $p < 0.05$) than patients in group A. Twenty-one of 29 patients (72 percent) with a control mean right atrial pressure of less than 14 mm Hg responded to 100 mg of hydralazine, whereas this dose was effective in only 5 (31 percent) of 16 patients with a higher pressure value ($p < 0.02$).

In conclusion, the doses required for effective hydralazine therapy in patients with severe heart failure are variable and are generally higher than those utilized in hypertensive patients. This may be related to varying degrees of vascular hyporesponsiveness or drug malabsorption, or both, observed in states of high venous pressure. The failure of hydralazine to produce clinical improvement in an individual patient may therefore be due to the administration of subtherapeutic quantities of the drug.

Hydralazine produces significant hemodynamic and clinical improvement in many patients with severe chronic congestive heart failure.[1–5] The drug reduces impedance to left ventricular outflow, thereby substantially increasing cardiac output and stroke volume. With institution of maintenance therapy, dyspnea and fatigue diminish, and hemodynamic and clinical benefits are sustained during long-term outpatient use.[3,4]

Despite early favorable reports, more recent studies have indicated that the response to hydralazine therapy in patients with heart failure is variable.[6–10] Whereas marked symptomatic improvement occurs in many patients,[1,5] others experience little objective clinical benefit[6–8] and a significant number of patients manifest only minimal hemodynamic responses.[9–11] Because previous studies have utilized fixed doses of the drug, it is not known whether the limited response in some patients is due to the administration of insufficient quantities of the drug or to the patients' inability to respond favorably to the drug's pharmacologic effects. To resolve this question, we evaluated the hemodynamic effects

of progressively larger doses of hydralazine in patients with heart failure who failed to respond to conventional doses.

Methods

Patients: We evaluated 45 consecutive patients with severe chronic congestive heart failure refractory to optimal conventional therapy with digitalis and diuretic agents. All were in New York Heart Association functional class IV.[12] There were 34 men and 11 women with an age range of 39 to 89 years (mean 64). All patients had persistent dyspnea at rest or on minimal exertion and progressive fatigue or azotemia, or both, with increments in diuretic dosage. The cause of the heart failure was idiopathic cardiomyopathy in 15 patients, ischemic cardiomyopathy in 21 and advanced valve regurgitation of rheumatic origin in 6 (affecting the mitral valve in 3, the aortic valve in 2 and both valves in 1); 3 patients had had prosthetic valve replacement (of the mitral valve in 1 and both the aortic and mitral valves in the other 2).

The diagnosis was based on clinical, electrocardiographic, echocardiographic and radioisotopic criteria and was confirmed with cardiac catheterization studies in 22 patients. Eight patients had clinical or angiographic evidence of severe mitral regurgitation. The duration of heart failure ranged from 2 to 8 years. Normal sinus rhythm was present in 35 patients, atrial fibrillation in 5 and ventricular pacemaker rhythm in 5. Symptoms persisted despite therapeutic doses of digoxin and furosemide, the latter in daily doses of 80 to 400 mg. Six patients were evaluated after an empiric trial of oral hydralazine (150 to 300 mg daily) had failed to produce clinical improvement.

All patients were studied during a period of relative clinical stability. No patient had sustained a myocardial infarction within 3 months or had an acute exacerbation of congestive heart failure within 7 days before evaluation. Maintenance therapy with prazosin or hydralazine was withheld for at least 2 weeks before the present study.

Hemodynamic measurements: After written informed consent was obtained from the patient, right heart catheterization was performed with a triple lumen flow-directed balloon-tipped catheter (Edwards or Instrumentation Laboratories) through which measurements of right atrial, pulmonary arterial and pulmonary capillary wedge pressures were made. Arterial cannulas were inserted percutaneously or by cutdown procedure into the radial artery in 39 patients; in the other 6, systemic arterial pressure was measured using standard cuff methods. All measurements were made with zero reference level at the mid axillary line with the patient supine. Left ventricular filling pressure was measured as mean pulmonary capillary wedge pressure or as pulmonary arterial diastolic pressure after its identity with wedge pressure was established. Cardiac output (by the thermodilution method) was determined in triplicate using a bedside cardiac computer (Instrumentation Laboratories) and iced injectate. Heart rate was derived from a continuously recorded electrocardiogram.

Before each dose of hydralazine was given, a stable control period was established and verified by repeated determinations of the following hemodynamic variables for a minimum of 3 hours with a variation of less than 10 percent: mean arterial pressure, heart rate, mean pulmonary arterial pressure, left ventricular filling pressure, mean right atrial pressure and cardiac output. All variables were redetermined every 30 minutes for 3 hours after each oral dose of hydralazine; and every 10 minutes for 30 to 40 minutes after each intravenous dose. A response to the drug was defined as a decrease in systemic vascular resistance greater than 20 percent from control values, the reduction persisting for at least 1 hour as assessed with three consecutive determinations.

Drug administration: After all medications were withheld for 12 to 24 hours and a stable control period was achieved, each patient received a single dose of 100 mg of hydralazine orally. If there was no response to this dose within 2 or 3 hours, the patient was given a dose of 150 to 200 mg orally. This second dose followed the initial dose by 18 to 24 hours, in 7 patients and by only 2 to 3 hours in the remaining 12. If there was no significant hemodynamic response to the second dose, 20 mg hydralazine was administered intravenously 2 to 3 hours later. In three patients who responded only to intravenous hydralazine single doses of 600 or 800 mg of the drug were administered orally 24 hours later after all hemodynamic variables had returned to control values. Maintenance therapy was instituted in each patient with the dose of hydralazine determined to be effective by invasive monitoring. Clinical symptoms were carefully recorded in each case.

Data analysis: Mean systemic and pulmonary arterial pressures were determined with electronic filtration; in patients with indirectly measured systemic pressures, mean pressure was calculated as diastolic pressure plus one-third of the systolic minus the diastolic pressure. Derived hemodynamic variables were determined as follows: Cardiac index = cardiac output/body surface area (liters/min per m^2); systemic vascular resistance = 80 × (mean arterial pressure − mean right atrial pressure)/cardiac output (dynes s cm^{-5}); and pulmonary vascular resistance = 80 × (mean pulmonary arterial pressure − left ventricular filling pressure/cardiac output (dynes s cm^{-5}).

For each patient, the dose of hydralazine that produced a significant decrease in systemic vascular resistance was selected as the effective dose for that patient. All hemodynamic variables at the time of the maximal decrease in systemic vascular resistance were compared with the control values before administration of hydralazine utilizing the t test for paired data. The patients were then classified into two groups according to whether the effective dose of hydralazine was 100 mg (group A) or greater (group B). This dose was chosen as the point of separation because it is the maximal single dose of hydralazine currently used in patients with heart failure.[2] The underlying etiologic, pathophysiologic and hemodynamic variables in patients in groups A and B were compared using the t test for independent variables and the chi square method with the Yates correction for continuity. The responses to 100 mg of hydralazine were then evaluated in relation to the control value for mean right atrial pressure by analysis of variance utilizing the arc sine transformation for proportions[13] and the chi square method for 4 × 2 tables.

Results

Hemodynamic responses to effective doses of hydralazine (Table I): Twenty-six patients (group A) responded to the administration of the initial dose of 100 mg of hydralazine; 19 patients (group B, 42 percent) did not. In group B, a second dose of 150 to 200 mg was effective in 14 patients; 7 of these received the second dose 24 hours after and 7 received it within 3 hours after the initial 100 mg dose. No significant hemodynamic effects could be demonstrated in five patients even with a cumulative dose of 300 mg orally over 2 to 3 hours; however, all five patients subsequently responded to intravenous injection of 20 mg of hydralazine.

TABLE I

Summary of Hemodynamic Changes With Effective Doses of Hydralazine in Groups A and B

		Group A	Group B
Cardiac index (L/min per m^2)	C	1.94 ± 0.10	1.79 ± 0.09
	H	2.98 ± 0.16*	2.84 ± 0.18*
Left ventricular filling pressure (mm Hg)	C†	21.7 ± 1.0	25.2 ± 1.2
	H	17.8 ± 0.9*	21.5 ± 1.2‡
Mean arterial pressure (mm Hg)	C	79.2 ± 2.0	83.9 ± 3.4
	H	66.1 ± 2.0*	73.3 ± 3.2*
Mean pulmonary arterial pressure (mm Hg)	C	36.1 ± 1.4	39.8 ± 1.8
	H	33.0 ± 1.7*	37.8 ± 1.7

In both groups of patients, effective doses of hydralazine produced substantial increases in cardiac index and marked decreases in systemic vascular resistance associated with moderate reductions in left ventricular filling pressure and mean arterial pressure. Heart rate increased slightly in both groups and there were no overall changes in mean right atrial pressure (Table I).

The control cardiac index, mean arterial pressure, heart rate and systemic and pulmonary vascular resistances in groups A and B and the changes in these variables produced by hydralazine in the two groups were similar. Groups A and B were not significantly different with respect to the number of patients with ischemic heart disease (9 in group A, 12 in group B) or the number of patients with evidence of severe mitral regurgitation (6 in group A, 2 in group B).

Role of right atrial pressure and left ventricular filling pressure: Only two variables differed significantly in groups A and B. Patients in group B had higher control values for mean right atrial pressure (14.0 ± 1.5 versus 9.2 ± 1.3 mm Hg; $p < 0.025$) and left ventricular filling pressure (25.5 ± 1.2 versus 21.7 ± 1.0 mm Hg; $p < 0.05$) than those of patients in group A (values expressed as mean ± standard error of the mean). Only 5 (19 percent) of the 26 patients in group A had a mean right atrial pressure of 14 mm Hg or greater, compared with 11 (58 percent) of 19 patients in group B ($p < 0.02$). The changes in mean right atrial and left ventricular filling pressures during hydralazine therapy in the two groups were similar.

Figure 1 demonstrates that the higher the control mean right atrial pressure, the smaller was the decrease in systemic vascular resistance with 100 mg doses of hydralazine (linearity significant at $p < 0.025$ by analysis of variance) and the fewer the number of patients who responded to this dose ($p < 0.05$ by chi square analysis). Twenty-one (72 percent) of 29 patients with a mean right atrial pressure at less than 14 mm Hg responded to 100 mg of hydralazine, compared with only 5 (31 percent) of 16 patients with a higher pressure value ($p < 0.02$). Five of the eight patients whose mean right atrial pressure was 5 mm Hg or less in the control period had a greater than 20 percent decrease in mean arterial pressure with the 100 mg dose of hydralazine; this decrease was accompanied by dizziness in four of the five. Symptomatic hypotension did not recur in these four patients when the dose of hydralazine was reduced to

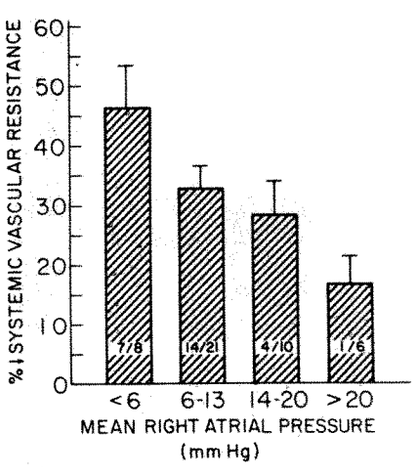

FIGURE 1. Relation between the control mean right atrial pressure and the percent decrease (% ↓) in systemic vascular resistance observed after the administration of single oral doses of 100 mg of hydralazine in 45 patients. Data expressed as mean ± standard error of the mean. The proportion of patients who responded to hydralazine at each level of mean right atrial pressure is shown within each **bar.**

75 mg. Of the 37 patients with a mean right atrial pressure greater than 5 mm Hg, only 1 (with a mean right atrial pressure 9 mm Hg) had a greater than 20 percent decrease in this pressure with the 100 mg dose; this decrease was accompanied by dizziness, which did not recur with a subsequent reduction in dosage to 75 mg.

Massive drug dosage: In three of the five patients who responded only to intravenous hydralazine therapy, an attempt was made to reproduce the effects of intravenous administration by administering massive oral doses of the drug after hemodynamic variables had returned to control values. In one patient a single oral dose of 600 mg proved effective; although the hemodynamic response was smaller than that observed after the 20 mg intravenous dose. In the other two patients, the response to a single oral dose of 800 mg of hydralazine was similar to that observed after intravenous administration of the drug. Figure 2 illustrates the response in one of these two patients. No significant hemodynamic changes had been seen in either patient with oral isosorbide dinitrate (single doses of 100 to 200 mg in one patient and 80 mg in the other) despite rapid responses in both patients to 10 mg of isosorbide dinitrate administered sublingually.

Maintenance therapy: In two patients hydralazine therapy was instituted with doses ranging from 75 to 800 mg orally in 38 patients and 20 mg intravenously in 2 patients, administered every 8 to 12 hours (Fig. 3, top). Daily doses, therefore, ranged from 150 to 2,400 mg daily orally and 60 mg daily intravenously (Fig. 3, bottom). After 1 week of maintenance therapy, four of the six patients who had failed to benefit from small empirically determined doses of the drug manifested sustained improvement with the larger doses determined by invasive testing. Headaches were observed in 12 patients (5 in group A and 7 in group B), but were generally mild and subsided in all cases despite continued administration of the drug. Symptomatic hypotension was observed in five patients (all in group A), as outlined earlier. Within 7 days of institution of therapy, administration of the drug was discontinued in three patients in group A (because of episodes of ischemic chest pain in one, severe nausea and vomiting in the second and hypotension and tachycardia in the third) and in three patients in group B (because of hypotension and tachycardia in one and severe nausea and vomiting in the other two).

Discussion

Dose requirements of hydralazine therapy: Our results indicate that the dose requirements of hydralazine in patients with severe chronic heart failure are highly variable and are generally much larger than those commonly utilized in antihypertensive therapy. Whereas hypertensive patients usually respond to doses of 50 mg or less,[14,15] patients with heart failure rarely demonstrate hemodynamic effects with single doses smaller than 75 mg.[1,16] Furthermore, in the present series of 45 patients, more than 40 percent required single doses of hydralazine that were substantially larger than 100 mg in order to reduce significantly systemic vascular resistance. Effective doses ranged as high as 800 mg orally as a single dose and up to 2,400 mg daily,

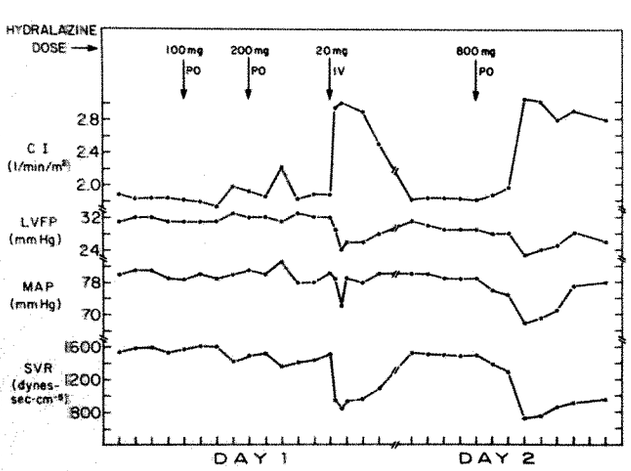

FIGURE 2. Graph showing no significant hemodynamic effects in a 62 year old man after the administration of a cumulative oral (PO) dose of 300 mg of hydralazine during a 3 hour period. However, marked responses were observed after the administration of 20 mg intravenously (IV). This response was reproduced 24 hours later under similar pretreatment conditions by the administration of a single dose of 800 mg orally. Each interval on the time scale represents 30 minutes. CI = cardiac index; LVFP = left ventricular filling pressure; MAP = mean arterial pressure; SVR = systemic vascular resistance.

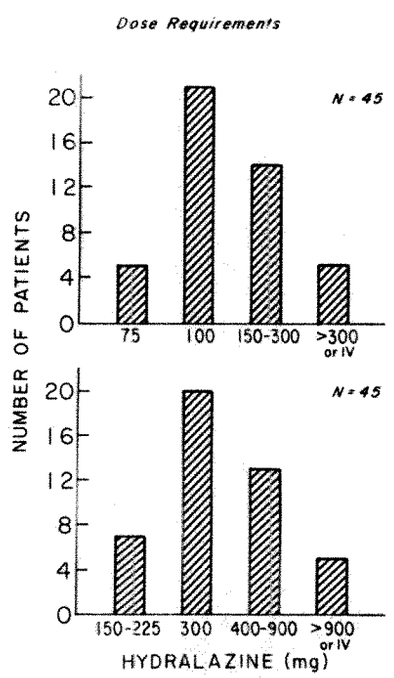

FIGURE 3. Dose requirements of hydralazine in 45 patients. The number of patients who responded at each dose level is illustrated. **Top,** effective single doses of the drug. **Bottom,** daily dosage requirements based on a dose schedule of every 8 to 12 hours.

and occasionally a patient responded only to intravenous administration. This may explain why previous investigators utilizing fixed schedules of smaller doses of hydralazine in patients with heart failure have reported inconsistent effects on cardiac index and little objective improvement in exercise tolerance.[3–11] Indeed, in four of our patients, the administration of these larger doses was effective in lessening dyspnea and fatigue, whereas smaller doses tried empirically before invasive testing had not produced symptomatic benefit. Although our study population may be preselected to some extent because of a tendency for patients to be referred after failure of an empiric trial with hydralazine (the true proportion of patients requiring large doses of the drug may be smaller), only six patients were evaluated after failure of previous hydralazine therapy.

Reasons for large dose requirements: The reasons for the unusually large dosage requirements for hydralazine in patients with severe heart failure are unknown. One might have expected patients with heart failure to be more sensitive than hypertensive patients to hydralazine because, in heart failure, compensatory reflexes that might counteract peripheral vasodilatation are attenuated,[17–21] hepatic metabolic inactivation of the drug may be diminished by the effects of hepatic venous congestion[22,23] and renal clearance of the agent is reduced.[16,24] However, recent evidence has indicated that the peripheral vasculature in patients with heart failure may be hyporesponsive to endogenous or exogenous vasodilator stimuli, either because of increased vascular stiffness secondary to an increase in sodium content within the arterial vessel walls or because of an increase in tissue pressure in edematous states.[25–27] This is consistent with our finding that patients requiring very large doses of hydralazine manifested higher ventricular filling pressures than did patients who responded to smaller doses. This may also explain why the development of tolerance to vasodilator therapy in hypertensive patients is associated with fluid retention and why responsiveness to the drug is restored after the administration of diuretic agents.[28,29]

Malabsorption of hydralazine may explain the failure of several patients to respond to massive doses of the drug (300 mg during a 3 hour period) administered orally although they had marked hemodynamic changes when small doses of the drug were administered intravenously. Since patients requiring very large doses demonstrated significantly higher mean right atrial pressures than did patients who responded to smaller doses, impaired drug absorption could be related to mesenteric venous congestion, a factor that may explain the relative ineffectiveness of other cardiovascular agents administered orally to patients with severe heart failure.[30–32] Indeed, two of our patients in group B did not respond to massive doses of isosorbide dinitrate administered orally, whereas small doses administered sublingually produced marked hemodynamic changes. Although enhanced metabolic inactivation of the drug by genetically rapid hepatic acetylator enzymes can result in a greater dosage requirement of hydralazine in some hypertensive patients,[24,33] the magnitude of this effect is too small to account for the unusually large doses needed by the patients in our group B and would not explain the ineffectiveness in these patients of other orally administered drugs metabolized by other enzyme systems.

Ribner et al.[11] suggested that patients with a high level of systemic vascular resistance before treatment may not respond to hydralazine because the effectiveness of vasodilators in patients with severely limited cardiac reserve is impaired. A major limitation of their study is the use of a fixed schedule of hydralazine administration with an upper dosage limit of 400 mg daily. By using progressive increments in dosage where indicated, we could find no differences in the pretreatment systemic vascular resistance between patients in groups A and B. Furthermore, the hemodynamic responses to effective doses of hydralazine were similar qualitatively and quantitatively in both groups, the only difference being the dose of the drug needed to produce the observed hemodynamic effects.

Side effects of large dose hydralazine therapy: In spite of these very large doses of hydralazine, acute adverse reactions were no more frequent in patients in group B than in those in group A. In fact, symptomatic hypotension was observed only with doses of 100 mg and only in patients in group A with low mean right atrial pressure. An initial dose of 75 mg of hydralazine seems warranted, therefore, in patients whose pretreatment mean right atrial pressure is less than 6 mm Hg. Whether long-term therapy will place patients in group B at greater risk of having hydralazine-induced systemic lupus erythematosus than group A remains to be determined.[34,35]

Implications: This study underscores the need for the administration of unusually large doses of hydralazine to produce significant improvement in left ventricular performance in patients with severe chronic heart failure. The dose required is highly variable (75 mg to 800 mg as a single dose) and is generally larger than that usually needed in hypertensive patients. In more than 40 percent of patients, significant hemodynamic effects are seen only with single doses greater than 100 mg, and occasionally a patient will respond only to intravenous administration of the agent. As a result, the failure of hydralazine to produce clinical improvement in an individual patient may be due to the administration of subtherapeutic quantities of the drug. Verification and quantification of hemodynamic changes by invasive studies may be necessary in patients who fail to respond to small empirically determined doses.

CARDIAC ARRHYTHMIAS: Mechanisms and Management

Cardiovascular Clinics, Volume 11, Number 1.

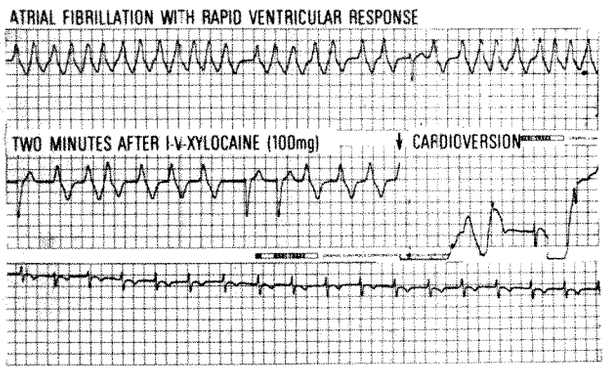
Guest Editor: **Agustin Castellanos,** MD, Professor of Medicine, Director, Clinical Electrophysiology, University of Miami School of Medicine, Miami, Florida.

Dr. Castellanos and some of the most respected authorities in the field have masterminded a concise, no-nonsense volume of practical advice that you will use again and again in your daily practice.

This handy book gives you detailed information on all the types of arrhythmias as well as on methods of diagnosis, treatment, and management. Particularly useful is the extensive coverage of the latest developments in the pharmacologic management of arrhythmias. Pertinent aspects of electrocardiographic diagnosis and assessment are discussed throughout.

About 350 pages. Illustd. About $37.50. Ready May 1980. Order #1684-8.

The Editor-in-Chief of the Cardiovascular Clinics is Albert N. Brest, MD.



The illustration above is from *Castellanos:* **Cardiac Arrhythmias.** It shows the slowing of a rapid ventricular rate during atrial flutter-fibrillation following intravenous infusion of 100 mg lidocaine (Xylocaine).

Contents and Contributors:

Indications for His Bundle Recordings, *Anthony N. Damato, Antonio R. Caracta, Prasad S. Vadde.* Sick Sinus Syndrome: Mechanisms and Management, *Brian J. Gaffney, Alan G. Wasserman, Alberto Rotsztain, Jorge C. Rios.* Supraventricular Tachycardia: Mechanisms and Treatment, *Ruey J. Office Cardiology

Dr. Robert O. Brandenburg, Sr., and eighteen of his colleagues from the Mayo Clinic give you a wealth of information based on their vast experience in treating ambulatory cardiovascular patients in an office practice. The effective use of noninvasive techniques is emphasized throughout. **Robert O. Brandenburg, Sr.,** MD, Guest Editor. 308 pp. 119 ill. $37.50. Feb. 1980. Order #1118-8.

Anesthesia and the Patient with Heart Disease

The practical anesthetic management of the cardiac patient scheduled for non-cardiac surgery is discussed by 12 eminent physicians. **Burnell R. Brown, Jr.,** MD, PhD, Editor. 193 pp. Illustd. $20.00. Jan. 1980. Order #1260-5.

On 30-day approval, please send and bill me for a copy of Castellanos: **Cardiac Arrhythmias.** #1684-8. Also send the books I have indicated below:

- ☐ Brown: **Anesthesia and the Patient with Heart Disease.** $20.00. Jan. 1980. #1260-5.
- ☐ Brandenburg: **Office Cardiology.** $37.50. Feb. 1980. #1118-8.
- ☐ Willerson: **Nuclear Cardiology.** $35.00. May 1979. #9329-X.

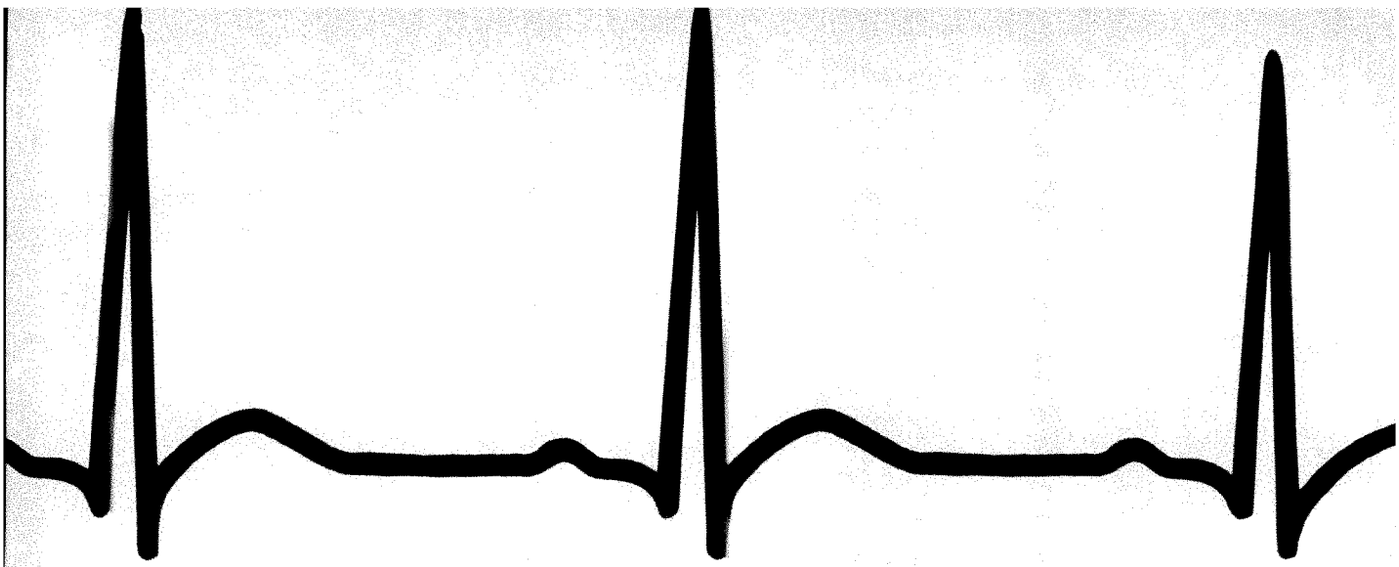
F. A. DAVIS COMPANY
1915 ARCH STREET
PHILADELPHIA, PENNSYLVANIA 19103



Imagine our excitement at becoming

Not that we're surprised. It's what we intended all along. What *did* surprise us is that it happened so fast.

That's because, since our beginnings in 1972, we haven't spent our time measuring our success, but creating it.

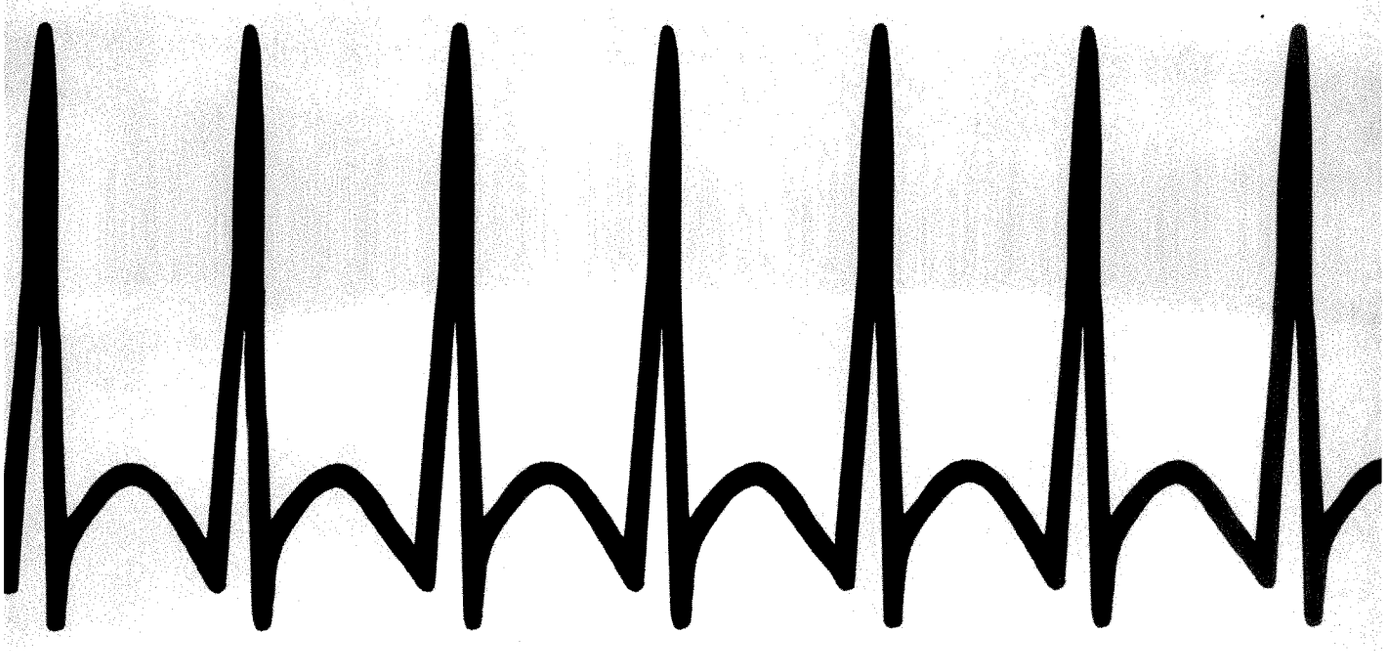
Like many other services in the long-term ECG (Holter) recording field, we saw that the main focus of the cardiologist was diagnosis and treatment, not maintaining complex and expensive equipment. Or tedious examination of twenty-four hour ECG recordings. Or time-consuming quality control. The need is for accurate data, clearly and quickly reported.

But we also saw something our competitors didn't see—room for improvement. So we decided to take the lead. Make the commitment.

There was more room than we thought: Room for re-inventing ECG recording techniques with the first miniaturized, two lead FM cassette recorder with a built-in timing track. For introducing the first digital computer-assisted playback system. For replacing the error-prone, rapid-fire Holter superimposition method with the operator controlled Stein/Peterson™ Examination Technique (with the heartfelt thanks of many a bleary-eyed examiner). For greatly improved data formating so that reports can be interpreted at a glance. For remote print-out terminals that can provide twenty-four hour delivery in cities like Los Angeles, Dallas, Chicago, Philadelphia, San Francisco, Cleveland and of course, Boston and New York (with more cities to come).

The list is long. The results have been impressive.

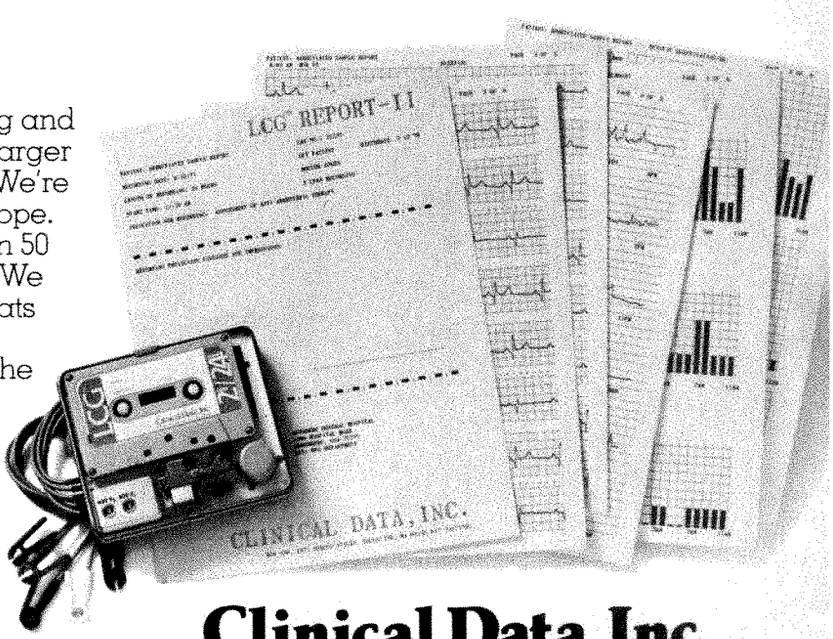
Clinical Data is today the largest and most



number one.

comprehensive long-term ECG recording and reporting service in America. Five times larger than our nearest competitor, we're told. We're the only service that's truly national in scope. We have over 100 employees – more than 50 of them medically trained professionals. We examine hundreds of millions of heartbeats and prepare thousands of reports every month. Hundreds of cardiologists across the nation depend on our reports for accuracy, clarity, and many extra features that are simply unavailable elsewhere.

We'd like to share our excitement with you. For your free detailed brochure and sample LCG Report-II™ write to us at 1371 Beacon Street, Brookline, Massachusetts 02146. Or call toll free 800-225-9180.

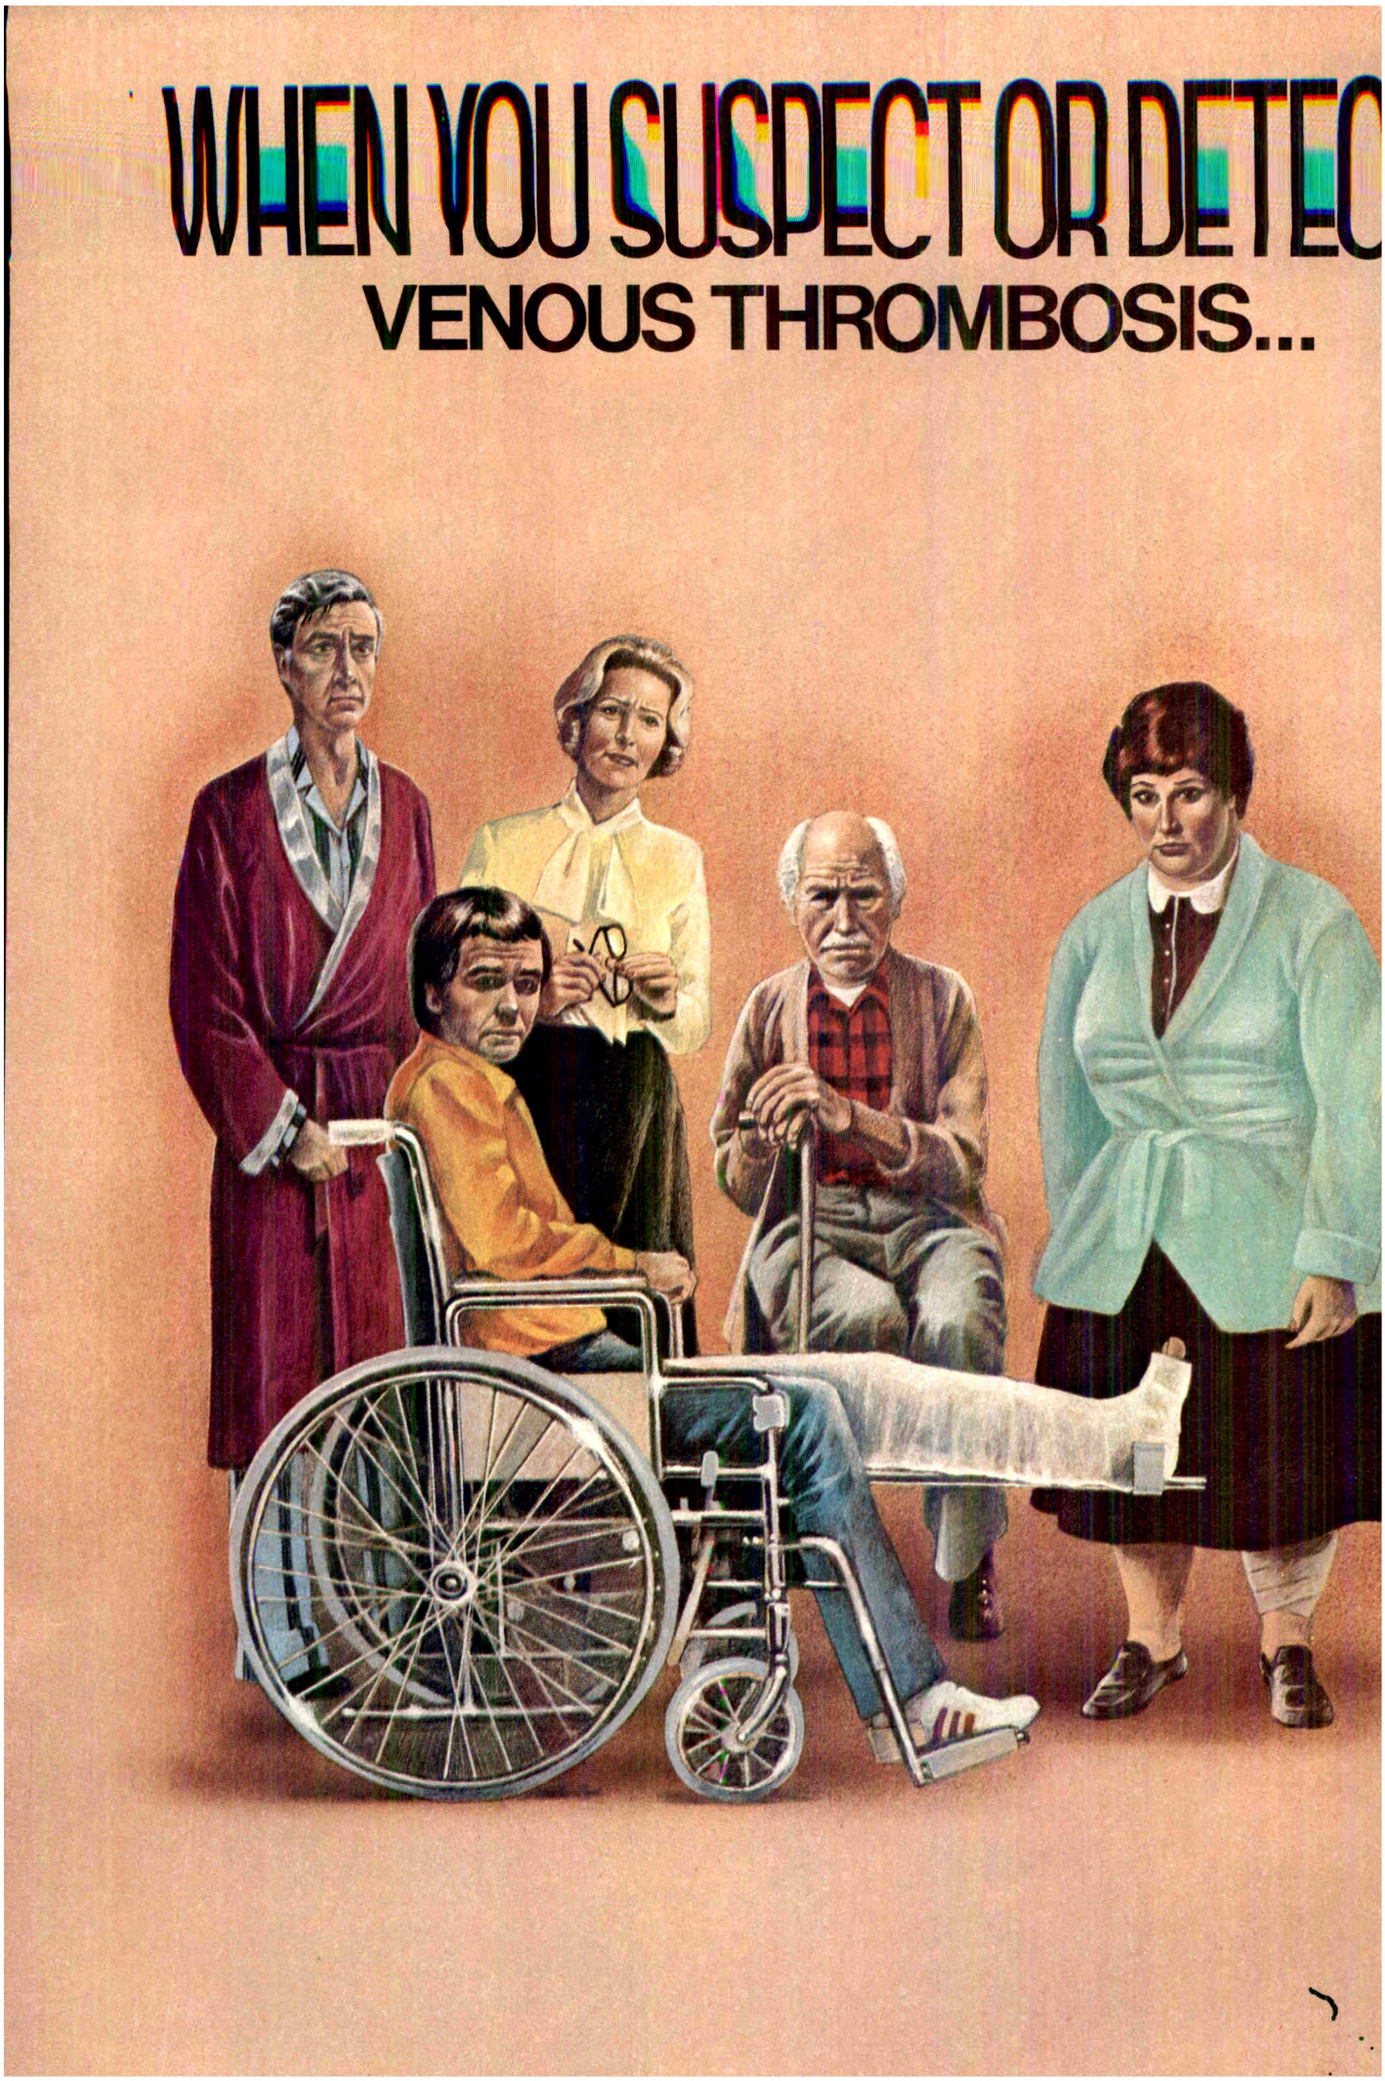


Clinical Data, Inc.

Making a long-term commitment to long-term recording.

WHEN YOU SUSPECT OR DETEC

VENOUS THROMBOSIS...



Thromboembolism: a high risk among patients with one or more of these factors...

Advanced age
Fractures of lower limb
Hip surgery
Pelvic or abdominal surgery with extensive dissection
Previous venous thromboembolism
Congestive cardiac failure
Cancer surgery
Obesity
Varicose vein surgery

Incidence of venous thrombosis or abnormal scans as shown by ^{125}I-fibrinogen screening in selected high-risk medical-surgical patients

Category	Incidence
Elective surgery	
Major abdominal thoracic/gynecologic	11-65%[1,2]
Retropubic prostatectomy	28-50%[1,2]
Transurethral prostatectomy	4%[1,2]
Emergency surgery	
Hip fracture	48-74%[1,2]
Childbirth	3%[1,2]
Medical	
Myocardial infarction	23-38%[1,2]
Stroke	60%[1]

ORAL ANTICOAGULATION:
Often indicated to lower the risk of thromboembolic complications.

*For selected patients who have had a large infarct, a history of previous infarction or angina, severe hypotension or shock, chronic atrial fibrillation, congestive heart failure, past history of venous thrombosis or embolism or complications requiring a prolonged period in bed.

Endo Laboratories DUPONT

COUMADIN is an Endo registered U.S. trademark.

The oral anticoagulant of choice:

Tablets
COUMADIN®
crystalline warfarin sodium

singled out by more than 20 years of experience

Effective prophylaxis and treatment of venous thrombosis
Effective prophylaxis and treatment of pulmonary embolism
Effective treatment of atrial fibrillation with embolization
Effective adjunctive treatment of coronary occlusion

Initiation of therapy

Induction—40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response

- dosage must be individualized according to patient's prothrombin time
- frequent laboratory monitoring is recommended
- determine prothrombin time daily until results fall within the therapeutic range—1.5 to 2.5 times normal
- afterwards, prothrombin time must be determined periodically to monitor the patient's course

Maintenance of anticoagulation

- 2-10 mg, for most patients (scored tablets allow flexibility and accurate titration)
- dose and interval should be adjusted according to the individual patient's prothrombin time response

Duration of anticoagulation

- should be individualized for each patient
- in general, should be continued until danger of thrombosis and embolism has passed

Recommendations of prominent clinicians on duration of therapy

in myocardial infarction[3,4*]	1-3 years* (reevaluate at least every 6 months)
in pulmonary embolism[4,5]	6 weeks-6 months
in deep vein thrombosis[4,5]	6 weeks-6 months

Before prescribing, please see full product information on next page.

COUMADIN® Tablets
for long- and short-term oral anticoagulation...
crystalline warfarin sodium, U.S.P.*

DESCRIPTION COUMADIN (crystalline warfarin sodium) a prothrombinopenic anticoagulant, is chemically crystalline sodium warfarin isopropanol clathrate. The crystallization of warfarin sodium virtually eliminates trace impurities present in amorphous warfarin sodium, thus achieving a crystalline product of the highest purity. Warfarin* is the coined generic name for 3-(α-Acetonylbenzyl)-4-hydroxycoumarin. On a dose-for-dose basis, COUMADIN (crystalline warfarin sodium) is therapeutically equivalent to amorphous warfarin sodium.

ACTIONS COUMADIN and other coumarin anticoagulants act by depressing synthesis in the liver of several factors which are known to be active in the coagulation mechanisms in a variety of diseases characterized by thromboembolic phenomena. The resultant **in vivo** effect is a sequential depression of Factors VII, IX, X and II. The degree of depression is dependent upon the dosage administered. Anticoagulants have no direct effect on an established thrombus, nor do they reverse ischemic tissue damage. However, once a thrombosis has occurred, anticoagulant treatment aims to prevent further extension of the formed clot and prevents secondary thromboembolic complications which may result in serious and possible fatal sequelae.

After oral administration, absorption is essentially complete, and maximal plasma concentrations are reached in 1 to 9 hours. Approximately 97% is bound to albumin within the plasma. COUMADIN usually induces hypoprothrombinemia in 36 to 72 hours, and its duration of action may persist for 4 to 5 days, thus producing a smooth, long lasting response curve. Little is known of the metabolic pathways involved in the biotransformation of oral anticoagulants in man. However, their metabolites appear to be eliminated principally in the urine.

INDICATIONS Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Pregnancy — COUMADIN is contraindicated in pregnancy because the drug passes through the placental barrier and may cause fatal hemorrhage to the fetus in utero. Furthermore, there have been reports of birth malformations in children born to mothers who have been treated with warfarin during pregnancy. Women of childbearing potential who are candidates for anticoagulant therapy, should be carefully evaluated and the indications critically reviewed with the patient. If the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks.

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1)central nervous system, (2)eye, (3)traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1)gastrointestinal, genitourinary or respiratory tracts, (2)cerebrovascular hemorrhage, (3)aneurysms—cerebral, dissecting aorta, (4)pericarditis and pericardial effusions, (5)subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis, or lack of patient cooperation. **Spinal puncture** and other diagnostic or therapeutic procedures with potential for uncontrollable bleeding. **Miscellaneous:** major regional lumbar block anesthesia and malignant hypertension.

WARNINGS Warfarin sodium is a potent drug with a half-life of 2½ days, therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN are given together, a period of at least 5 hours should elapse after the last intravenous dose and 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when warfarin sodium is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:

Lactation — coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora** — sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, severe allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN, thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN.

Concurrent use of anticoagulants with streptokinase or urokinase is not recommended and may be hazardous. (Please note recommendations accompanying these preparations.)

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma, collagen disease, congestive heart failure, diarrhea, elevated temperature, hepatic disorders—infectious hepatitis, jaundice, poor nutritional state, vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†, allopurinol, aminosalicylic acid, anabolic steroids, antibiotics, bromelains, chloral hydrate†, chlorpropamide, chymotrypsin, cimetidine, cinchophen, clofibrate, COUMADIN (crystalline warfarin sodium) overdosage, dextran, dextrothyroxine, diazoxide, dietary deficiencies, diuretics†, disulfiram, drugs affecting blood elements, ethacrynic acid, glucagon, hepatotoxic drugs, indomethacin, inhalation anesthetics, mefenamic acid, methyldopa, methylphenidate, metronidazole, monoamine oxidase inhibitors, nalidixic acid, oxolinic acid, oxyphenbutazone, phenylbutazone, phenyramidol, prolonged hot weather, prolonged narcotics, quinidine, quinine, salicylates, sulfinpyrazone, sulfonamides, long acting, thyroid drugs, tolbutamide, triclofos sodium, trimethoprim/sulfamethoxazole, unreliable prothrombin time determinations.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Diabetes mellitus, edema, hereditary resistance to coumarin therapy, hyperlipemia, hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids, alcohol†, antacids, antihistamines, barbiturates, chloral hydrate†, chlordiazepoxide, cholestyramine, COUMADIN underdosage, diet high in vitamin K (vegetables, fish, fish oil, onions), diuretics†, ethchlorvynol, glutethimide, griseofulvin, haloperidol, meprobamate, oral contraceptives, paraldehyde, primidone, rifampin, unreliable prothrombin time determinations, vitamin C.

†Increased and decreased prothrombin time responses have been reported.

*Present as crystalline sodium warfarin isopropanol clathrate.

A patient may be exposed to a combination of the above factors, some of which may increase or some decrease his sensitivity to COUMADIN. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (diphenylhydantoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN (crystalline warfarin sodium) include:

1. Minor or major hemorrhage from any tissue or organ — which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer, etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and a reaction consisting of hemorrhagic infarction and necrosis of the skin.

3. Priapism has been associated with anticoagulant administration, however, a causal relationship has not been established.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN patient aids are available to physicians on request.

The administration and dosage of COUMADIN must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K dependent Factors VII, X and II. These factors, in addition to Factor IX, are affected by coumarin anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic anticoagulation are 1½ to 2½ times the normal prothrombin time (e.g. 18 to 30 seconds, with a control of 12 seconds).

Induction — 40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response. The basis for the no-loading dose regimen is that the depression of Factors II, IX, and X are not accelerated by the administration of a loading dose.

Maintenance — Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy — The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery — The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN (crystalline warfarin sodium) be adjusted to maintain the prothrombin time at approximately 1½ to 2½ times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN with Heparin — Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in emergency situations to administer sodium heparin initially along with COUMADIN. The initial dose of heparin and injectable COUMADIN may be administered together in the same syringe. It should be noted that heparin may affect the prothrombin time, and therefore, when patients are receiving both heparin and COUMADIN, the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, at least 5 hours after the last intravenous injection or 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN (crystalline warfarin sodium), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN may suffice, and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can again be obtained.

SUPPLIED Tablets: COUMADIN (crystalline warfarin sodium). For oral use, single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous warfarin sodium lyophilized for intravenous or intramuscular use in a box of 6 units for use immediately after reconstitution.

50 mg: Unit consists of 1 vial, 50 mg sodium chloride, 10 mg thimerosal, 0.2 mg pH is adjusted with sodium hydroxide, accompanied by a 2 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief Heart Institute, Chaim Sheba Medical Center, Tel-Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon — indeed, *every physician* — should have a good basic knowledge of The Pre-Excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is broght a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

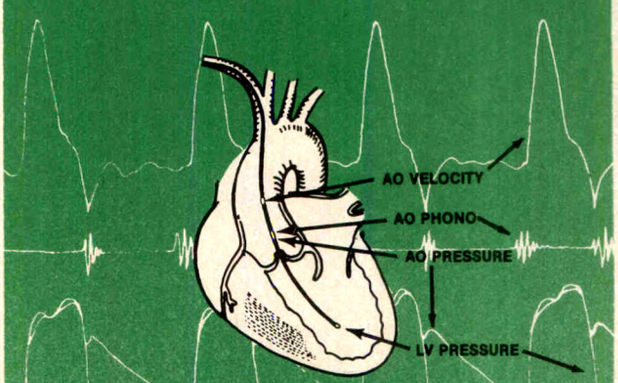
CATHETER-TIP TRANSDUCERS With a single catheter introduction ...

- **Single pressure recordings**
- **Multiple pressure recordings**
- **Multiple pressure with velocity recordings**
- **Phono recordings**



Millar MIKRO-TIP® Catheter Pressure Transducers provide the most accurate possible measurement of physiological pressures directly at the source. In addition, an electromagnetic fluid-velocity sensor may be incorporated for simultaneous measurement of velocity and pressure.

The MIKRO-TIP® pressure sensor was designed specifically for catheter-tip use. It features thermal stability, minimal drift, excellent linearity with negligible hysteresis, high natural frequency, large output signal with good signal-to-noise ratio, and insensitivity to "catheter whip". With a frequency response from dc to 20 kHz, it is also an excellent sensor for localized heart sounds.

Millar MIKRO-TIP® Catheter Pressure Transducers are available with one or more pressure sensors or with one fluid-velocity sensor together with one or more pressure sensors. Models are available in French sizes from 4F through 8F. You select the size and configuration that's right for your specific need.

For complete information, call or write Millar Instruments today.

Also...simultaneous fluid sampling or injection capabilities

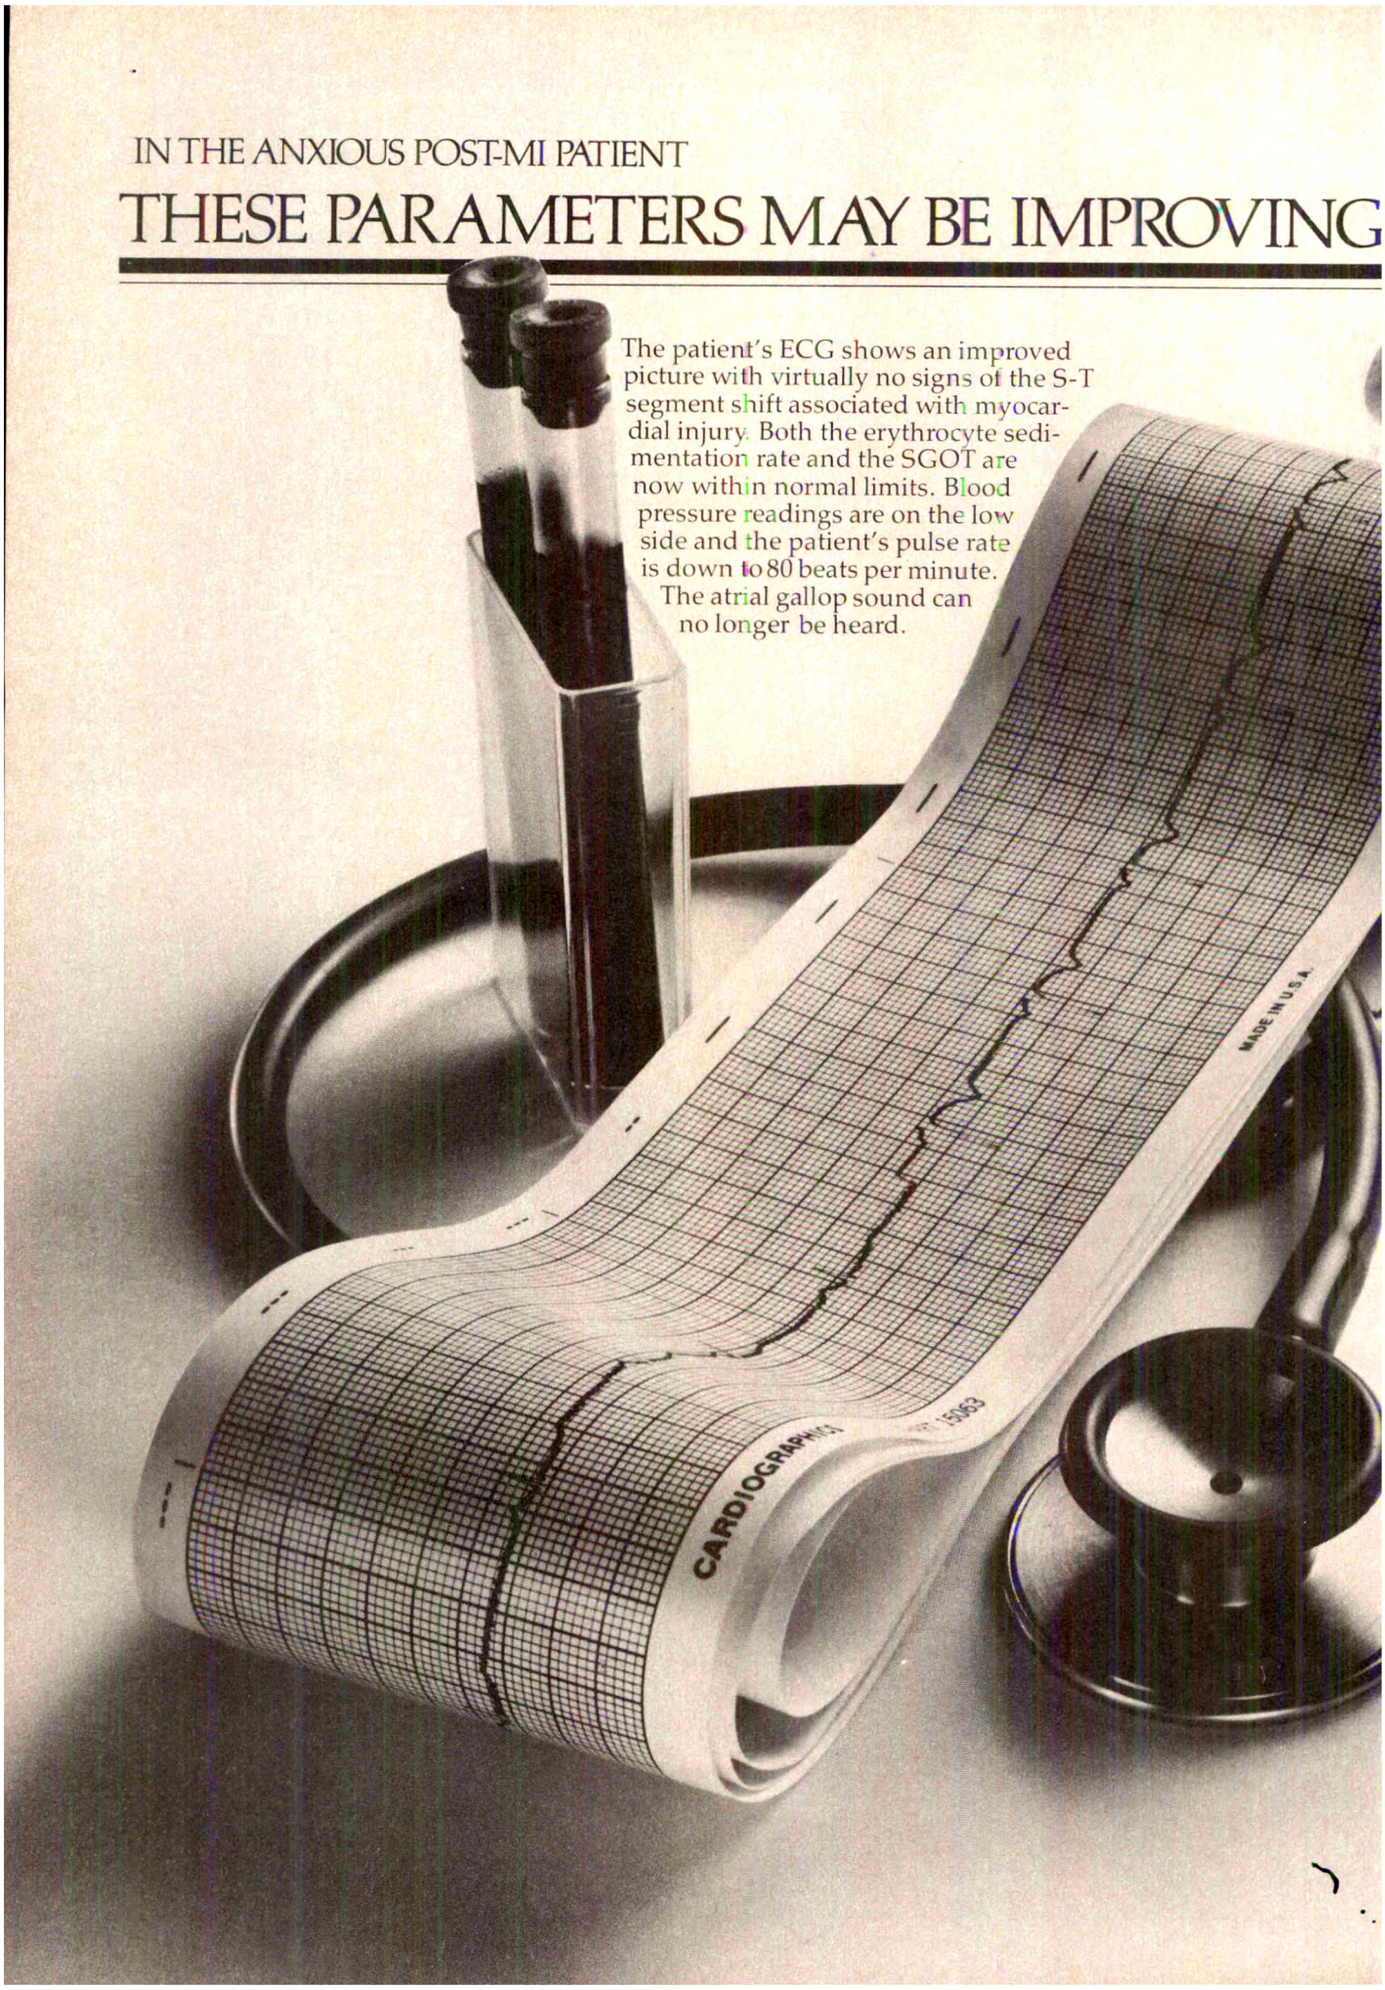
REPRESENTED INTERNATIONALLY—TELEX 791288

IN THE ANXIOUS POST-MI PATIENT

THESE PARAMETERS MAY BE IMPROVING



The patient's ECG shows an improved picture with virtually no signs of the S-T segment shift associated with myocardial injury. Both the erythrocyte sedimentation rate and the SGOT are now within normal limits. Blood pressure readings are on the low side and the patient's pulse rate is down to 80 beats per minute. The atrial gallop sound can no longer be heard.

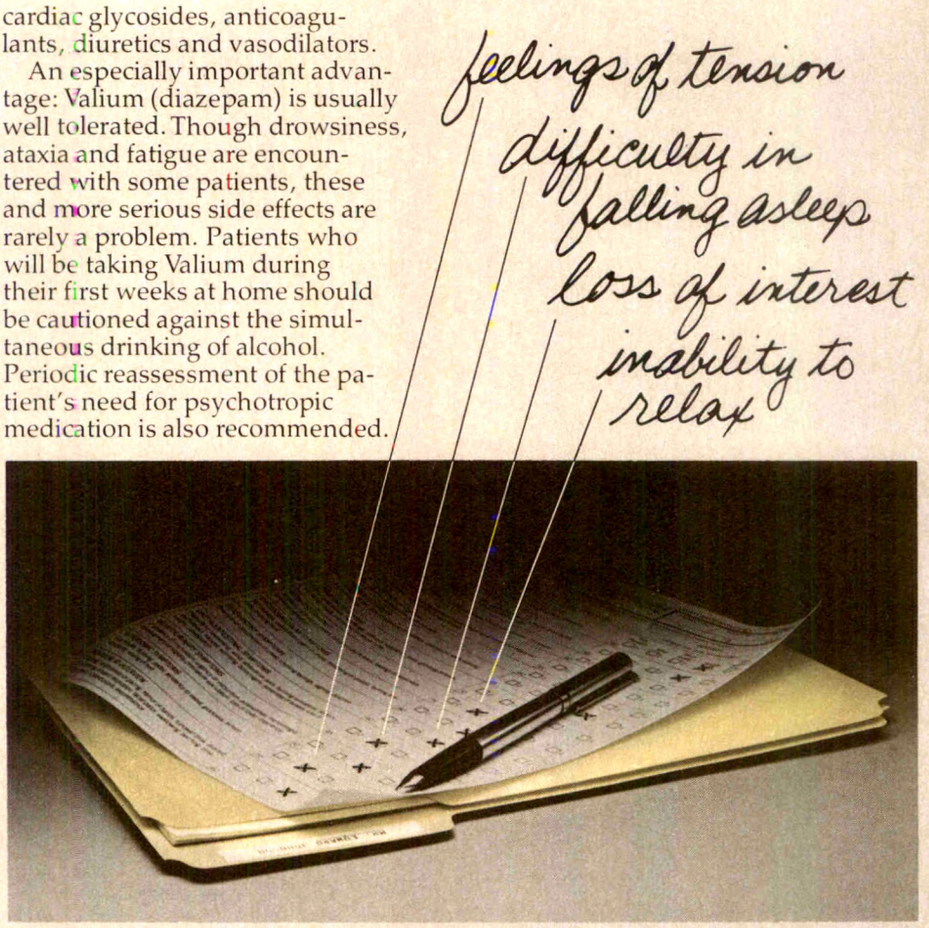
BUT THESE MAY NOT.

You've assured the patient, time and again, that he's making excellent progress, that all signs point to a marked improvement in his condition. He *seems* to understand... and yet, his excessive anxiety and psychic tension continue to pose problems.

For patients like this, adjunctive Valium (diazepam) can be particularly useful. Valium works promptly: patients often feel distinctly calmer in hours, usually report significant symptomatic relief within days. And once calmer and in better control of their emotions, they tend to be more optimistic as well and to enter more willingly into rehabilitative programs.

Valium can also alleviate the anxiety-linked insomnia so often seen in post-MI patients. In most cases, adding an *h.s.* dose of Valium to the usual *t.i.d.* schedule helps relieve "nighttime apprehensions" and encourages sleep. And Valium is used with most classes of primary medications, including cardiac glycosides, anticoagulants, diuretics and vasodilators.

An especially important advantage: Valium (diazepam) is usually well tolerated. Though drowsiness, ataxia and fatigue are encountered with some patients, these and more serious side effects are rarely a problem. Patients who will be taking Valium during their first weeks at home should be cautioned against the simultaneous drinking of alcohol. Periodic reassessment of the patient's need for psychotropic medication is also recommended.



VALIUM® (IV)
diazepam/Roche
2-mg, 5-mg, 10-mg scored tablets

TO REDUCE EXCESSIVE ANXIETY
TO MORE MANAGEABLE LEVELS

Before prescribing, please see following page for a summary of product information.

ROCHE

Valium® (diazepam/Roche)

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states, somatic complaints which are concomitants of emotional factors, psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders, athetosis, stiff-man syndrome; convulsive disorders (not for sole therapy).

The effectiveness of Valium (diazepam) in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice, periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

KATO®
(potassium chloride for oral solution)
20 mEq (1.5 g. KCl)

Prescribing Information

DESCRIPTION:
Spray-dried tomato powder containing 20 mEq potassium (equivalent to 1.5 g. KCl) per 6 grams powder (one dose) with natural and synthetic flavors, spices and colors. Benzoic acid and potassium benzoate added as preservatives. When reconstituted as directed, makes a pleasantly flavored, low sodium tomato juice drink. Each daily dose (2 packets) contains less than 10 mg. sodium.

INDICATIONS:
The prevention or correction of potassium deficit, particularly when accompanied by hypochloremic alkalosis in conjunction with thiazide diuretic therapy, in digitalis intoxication, or as the result of long-term corticosteroid therapy, low dietary intake of potassium, or excessive vomiting or diarrhea.

CONTRAINDICATIONS:
Potassium is contraindicated in severe renal impairment involving oliguria, anuria or azotemia; in untreated Addison's disease, familial periodic paralysis, acute dehydration, heat cramps, hyperkalemia from any cause. Potassium chloride should not be employed in patients receiving potassium-sparing agents such as aldosterone antagonists and triamterene.

PRECAUTIONS:
KATO is a concentrate and should be taken only after reconstituting with water as directed. This preparation, like other potassium supplements, must be properly diluted to avoid the possibility of gastrointestinal irritation. Do not use in patients with low urinary output or renal decompensation. Administer with caution; it is impossible to assess accurately the daily dose required. Excessive dosage may result in potassium intoxication. Frequent checks of the clinical status of the patient, ECG and/or plasma potassium level should be made. High plasma concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease.

ADVERSE REACTIONS:
Vomiting, diarrhea, nausea, and abdominal discomfort may occur. Gross overdosage may produce signs and symptoms of potassium intoxication: mental confusion, listlessness, paresthesia of the extremities, weakness and heaviness of legs, flaccid paralysis, hyperkalemia, ECG abnormalities, fall in blood pressure, cardiac arrhythmias and heart block. The characteristic changes in the ECG are disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, tall peaked T waves, etc.

TOXICITY:
Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

TREATMENT OF HYPERKALEMIA:
1. Dextrose solution 10% or 25% containing 10 units of crystalline insulin per 20 g. dextrose, given I.V. in a dose of 300cc to 500cc in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resin, orally or as retention enema. 3. Hemodialysis or peritoneal dialysis. 4. Elimination of potassium-containing foods and medicaments. Warning: Digitalis toxicity can be precipitated by lowering the plasma potassium concentration too rapidly in digitalized patients.

ADMINISTRATION AND DOSAGE:
Mix with water to make a pleasant tomato juice drink. Each 6 gram unit dose packet provides 20 mEq of potassium. Usual adult dose—1 packet of KATO mixed with about 2 ounces of water twice daily—supplies 40 mEq potassium per day. Take with meals or follow with ½ glass of water. Larger doses may be required, but should be administered under close supervision because of the possibility of potassium intoxication.

HOW SUPPLIED:
Cartons of 30 and 120 6 gram unit dose packets, 20 mEq each.

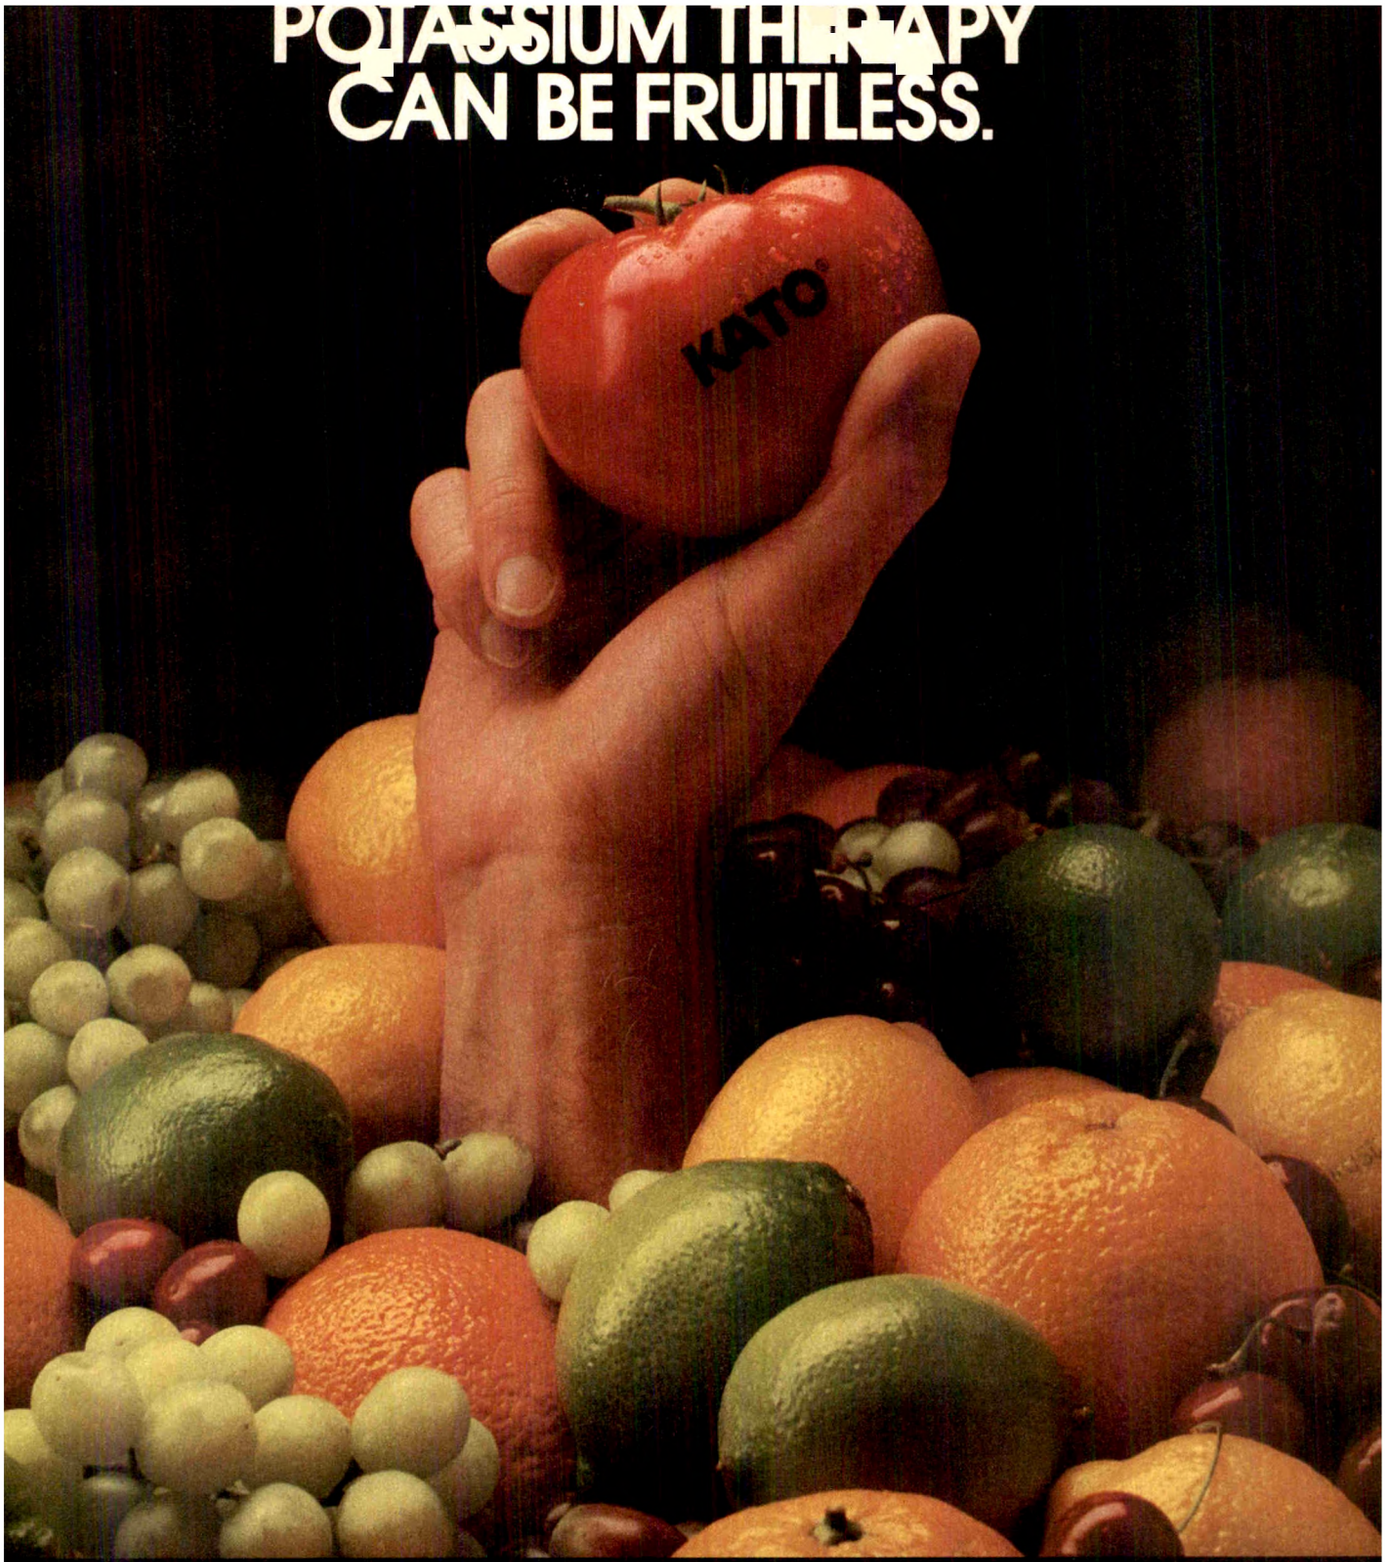
SYNTEX

SYNTEX PUERTO RICO, INC.
HUMACAO, PUERTO RICO 00661

POTASSIUM THERAPY CAN BE FRUITLESS.



Trying to smother the taste of potassium with sweet fruit flavorings never seems to work very well. It's like pouring salt straight into your orange juice—and just about as undrinkable for many patients. That's when a matter of taste becomes a problem of compliance.

KATO® (potassium chloride for oral solution) has the right kind of taste, the fresh tomato tang that [illegible] the saltiness of potassium chloride.

It provides the potassium salt of choice—the chloride—as a powder that mixes quickly with water, for the liquid dosage form preferred for safety. Each easy-to-use packet contains 20 mEq potassium chloride, with less than 5 mg sodium.

Offer your patients the tangy taste of KATO—the fruitless [illegible] for fruitful therapy.

KATO®
(potassium chloride for oral solution) 20 mEq (1.5 g. KCl)
Potassium with the tang of tomato.

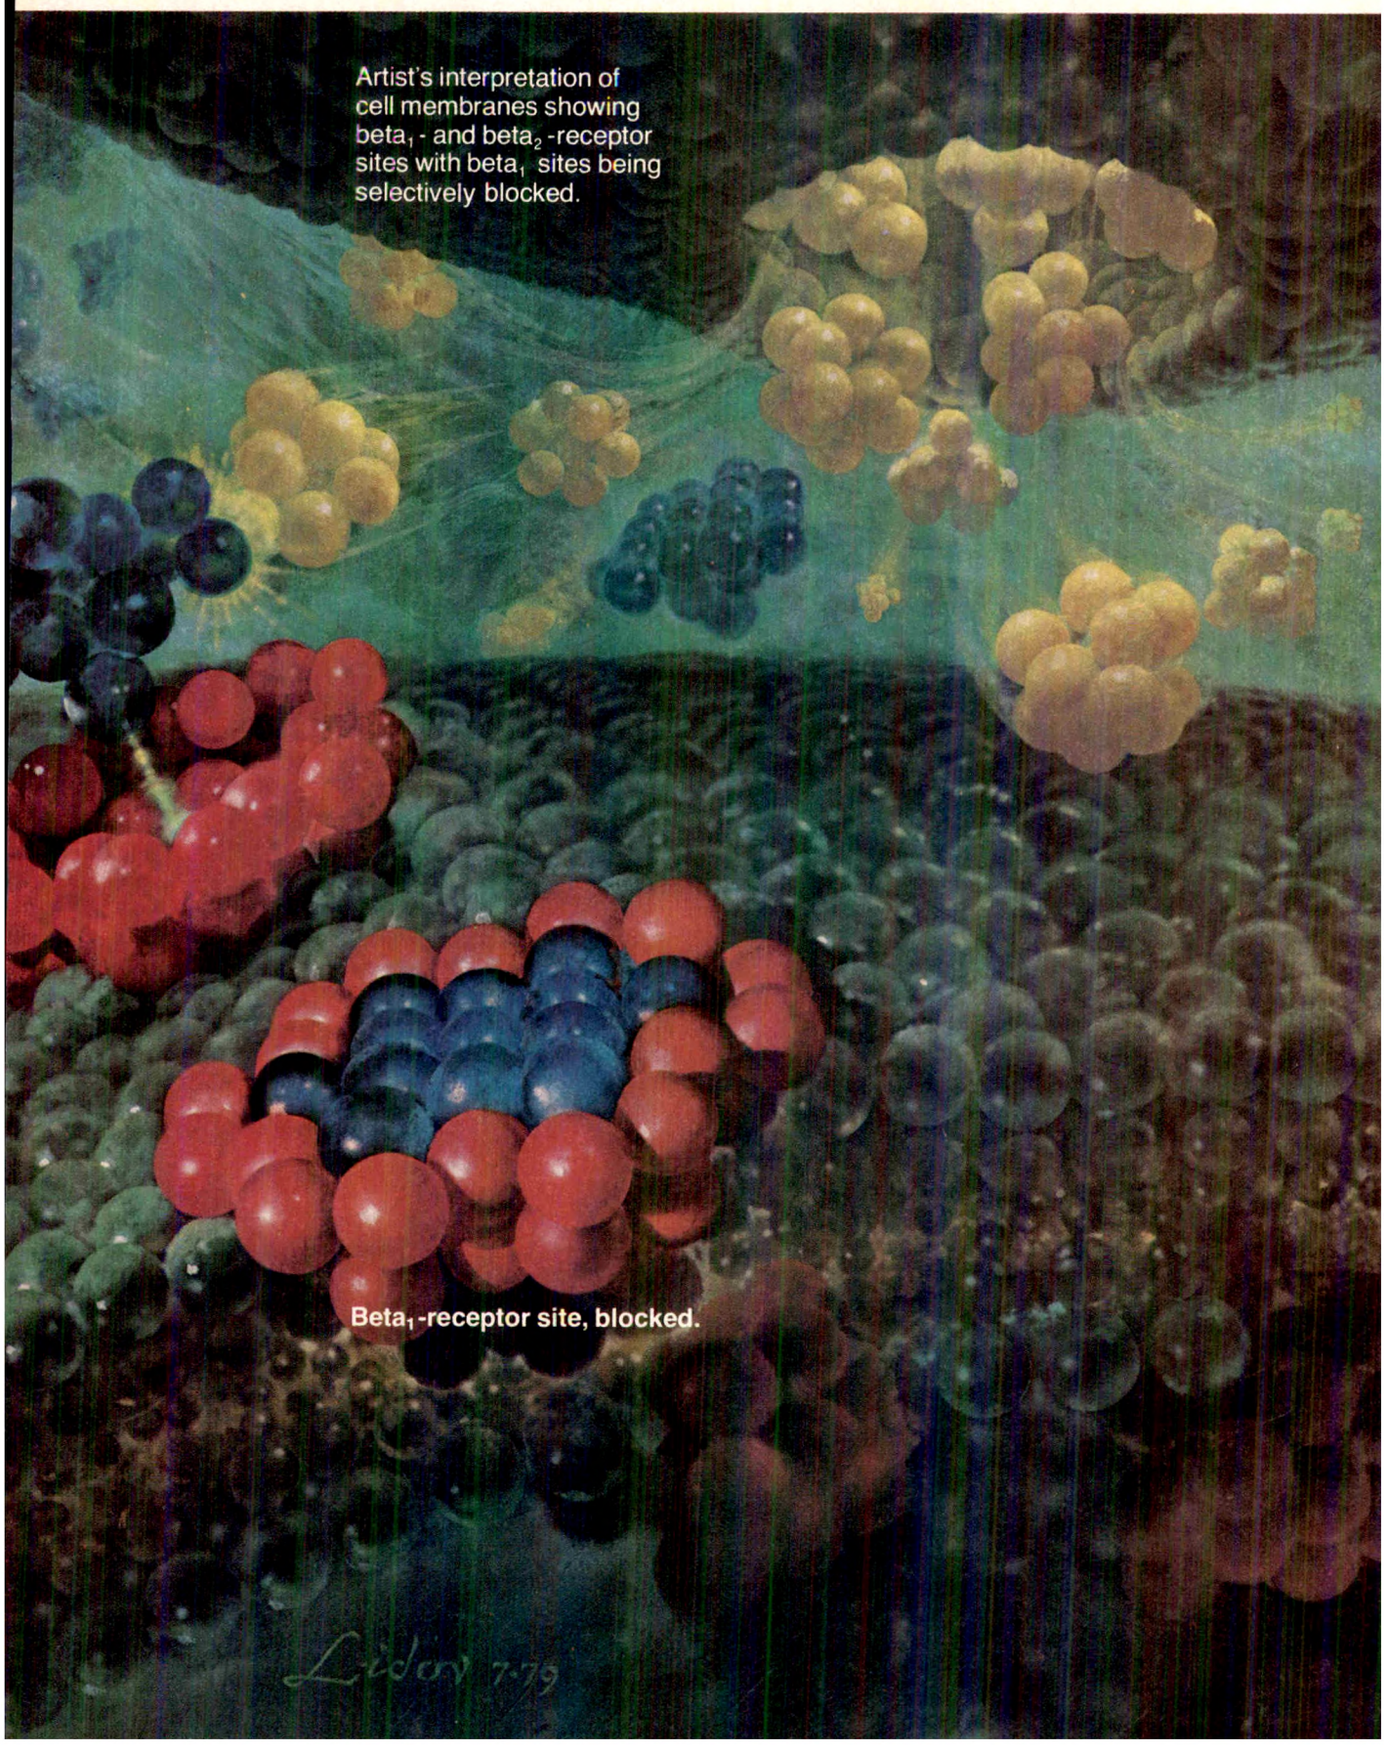
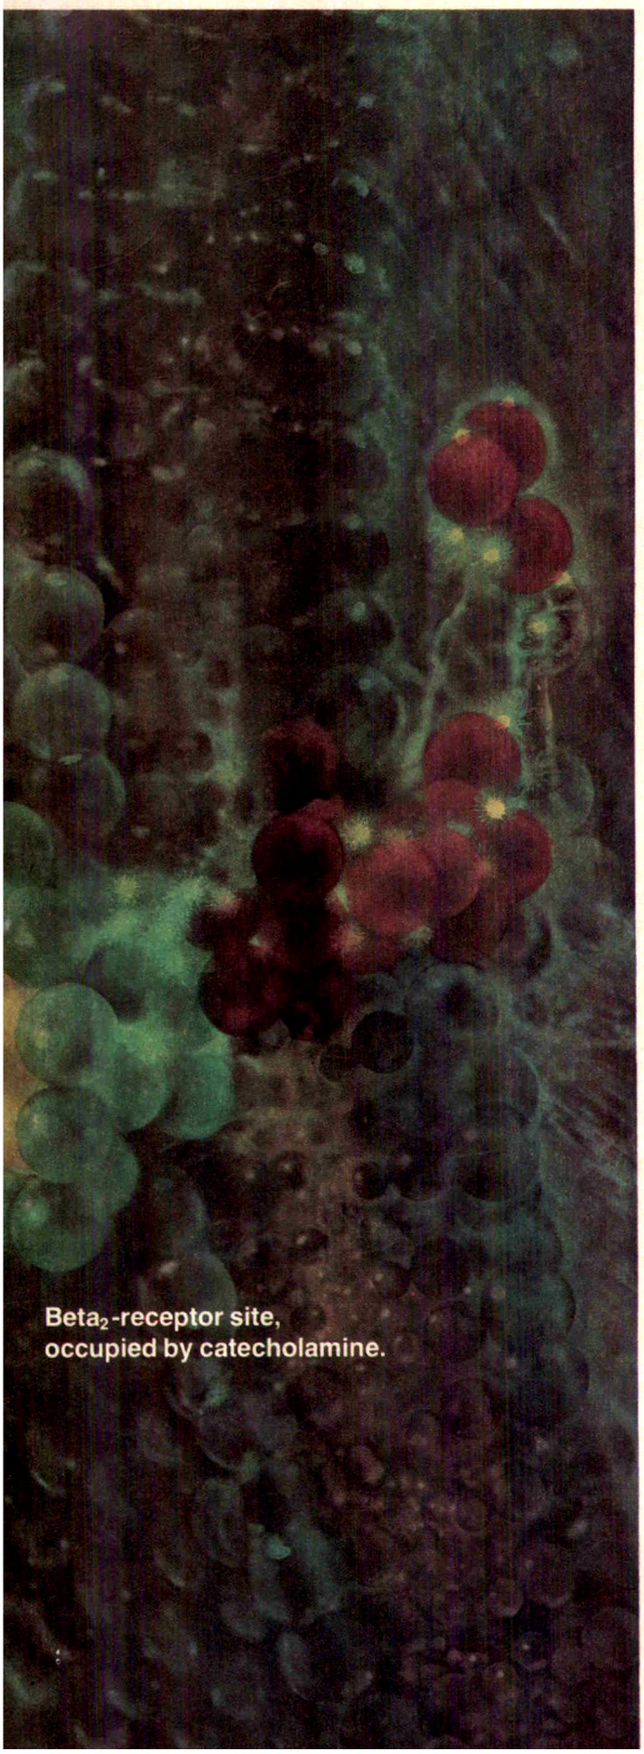
HUMACAO, PUERTO RICO 00661

the preferential effect



Lopressor®
metoprolol tartrate

works where it should—not where it shouldn't in hypertension



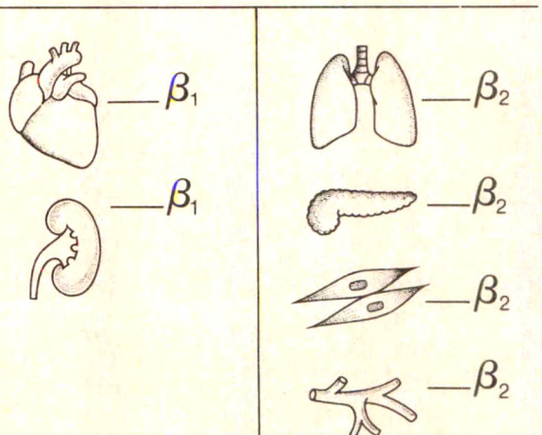
Beta$_2$-receptor site, occupied by catecholamine.

The beta blocker with a significant preference for beta$_1$ receptors in the heart*

Lopressor represents a major step forward in more specific beta blockade.

Unlike the nonselective beta blocker, propranolol, which indiscriminately blocks both beta$_1$ and beta$_2$ adrenoreceptors, Lopressor is relatively selective, that is, it exerts a preferential effect on beta$_1$ receptors in the heart—those involved in lowering blood pressure. Lopressor, at usual therapeutic doses, has a much lower affinity for beta$_2$ receptors.

Beta$_1$-and beta$_2$-receptor sites



Works where it should... not where it shouldn't.

*Hansson L, Werkö L: Beta-adrenergic blockade in hypertension. Am Heart J 93(3):394-402 (Mar.) 1977.

Please see next page for brief prescribing information.

Geigy

Lopressor®
metoprolol tartrate

works where it should... not where it shouldn't

Very well tolerated

- unlike traditional sympathetic inhibitors, there is usually no sedation, sexual dysfunction or postural hypotension with Lopressor
- most side effects mild and transient

The most frequently reported adverse reactions (which occurred in approximately ten out of 100 patients) are tiredness and dizziness. Depression and diarrhea have occurred in about five out of 100. Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effect of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**)

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Printed in U.S.A. 667292 (8/79) C79-22

*Not all members of the faculty will be speaking at each symposium.

PROGRAM TOPICS

(First two days)
Clinical applications
Introduction to imaging techniques:
- Gated blood pool
- Thallium perfusion
- First transit
- Thallium and gated blood pool tomography
- Myocardial pyrophosphate infarct

Instrumentation
Data processors/software
Radiopharmaceuticals

OPTIONAL WORKSHOP*

(Third day) Consultation on:
- Instrumentation
- Computer software
- Licensure
- Certificate of Need
- Third party reimbursement

*Workshop, conducted by Nuclear Cardiology Systems consultants, is designed solely for those physicians interested in establishing or adding instrumentation to a nuclear cardiology laboratory within the next 12 months.

REGISTRATION

Registration fee is $750. This fee covers all lectures, symposium abstracts, coffee breaks and luncheons. A full refund will accompany cancellations made up to two weeks in advance of the meeting. No refunds will be made after that date. However, a substitute may be sent in place of the original applicant. Symposium attendees are responsible for securing their own hotel reservations.

LIMITED REGISTRATION. LAS VEGAS, APRIL 18, 19 & 20.

FOR LATE REGISTRATION, CALL: (415) 928-0500

Applications to the symposium will be limited, so register early. Registration fee is $750 per person. Mail coupon or phone for reservations.

Nuclear Cardiology. I. Radionuclide Angiographic Assessment of Left Ventricular Contraction: Uses, Limitations and Future Directions

MONTY M. BODENHEIMER, MD, FACC
VIDYA S. BANKA, MD, FACC
RICHARD H. HELFANT, MD, FACC

Philadelphia, Pennsylvania

Radionuclide angiography has been increasingly utilized to evaluate left ventricular function in a wide variety of disease states. Comparison with contrast ventriculography has shown that radionuclide angiography is an accurate means of determining global ejection fraction. Moreover, studies have shown that this technique is of particular value in detecting the presence and severity of regional asynergy as, for example, in the delineation of a discrete aneurysm versus global asynergy as the cause of congestive heart failure.

The relative ease of repetitive examinations permits evaluation of left ventricular function under different conditions. Thus, radionuclide angiography is being increasingly used as a prognostic and therapeutic guide. In addition, it can be used during an acute intervention—for example, with administration of nitroglycerin to detect reversible asynergy or, as recently demonstrated by several groups, during exercise as a relatively sensitive and specific means to detect coronary heart disease.

In recent years, it has been increasingly recognized that the ability to assess the contractile state of the left ventricle provides invaluable diagnostic, therapeutic and prognostic information in a wide variety of cardiac diseases.[1–5] Up until now, however, invasive procedures such as contrast ventriculography have been the only methods whereby global and segmental left ventricular contraction could be accurately assessed. Since Blumgart and Yens[6] first used a radioactive tracer to evaluate velocity of blood flow in man, substantial improvements have been made in imaging devices, isotopes and computer techniques. Consequently, these techniques have been applied to radionuclide angiographic assessment of the heart and particularly the left ventricle.[7–11] Studies have included determination of ejection fraction and asynergy (and their response to both medical and surgical therapy) as well as stress radionuclide angiography to detect coronary heart disease. These techniques have been found repeatable, and measurements of both ejection fraction[12,13] and asynergy have correlated well with those obtained by contrast ventriculography.[12,14] In this paper, the status of radionuclide angiography will be reviewed.

Methods of Performing Radionuclide Angiography

Left ventricular contraction can be determined currently by one of two methods: first pass or gated equilibrium radionuclide angiography. Each technique has intrinsic advantages and disadvantages.

From the Division of Cardiology, Presbyterian-University of Pennsylvania Medical Center, and the Department of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania. This work was supported in part by a grant from the Mabel Pew Myrin Trust, Philadelphia, Pennsylvania. Manuscript received August 6, 1979; revised manuscript received October 23, 1979, accepted October 26, 1979.

Address for reprints: Richard H. Helfant, MD, Chief, Division of Cardiology, Presbyterian-University of Pennsylvania Medical Center, 51 North 39th Street, Philadelphia, Pennsylvania 19104.

First Pass Technique

The first pass technique of radionuclide angiography consists of rapidly injecting a radionuclide bolus of isotope into an antecubital or (occasionally) an external jugular vein and obtaining images, commonly 20 to 25/s although up to 100/s is possible, as the bolus passes through the right heart chambers, lung field and left heart chambers (Fig. 1, upper left). Most commonly a volume of 0.8 ml or less containing 12 to 15 mCi of technetium-99m sodium pertechnetate is used. Current-generation single crystal cameras permit counting rates of 30,000 to 80,000/s, whereas multicrystal cameras attain 150,000 to 250,000 counts/s. In addition to the type of imaging device used, other factors such as the size of the patient, quality of the bolus injection and type of collimation employed all affect obtainable count rate.

After data accumulation, the chamber of interest is identified or "flagged" (Fig. 1, lower left). A computer generates a time-activity curve, which is a plot of counts (y axis) seen by the "flagged" crystals versus time (x axis). As seen in Figure 1 (upper right), this represents

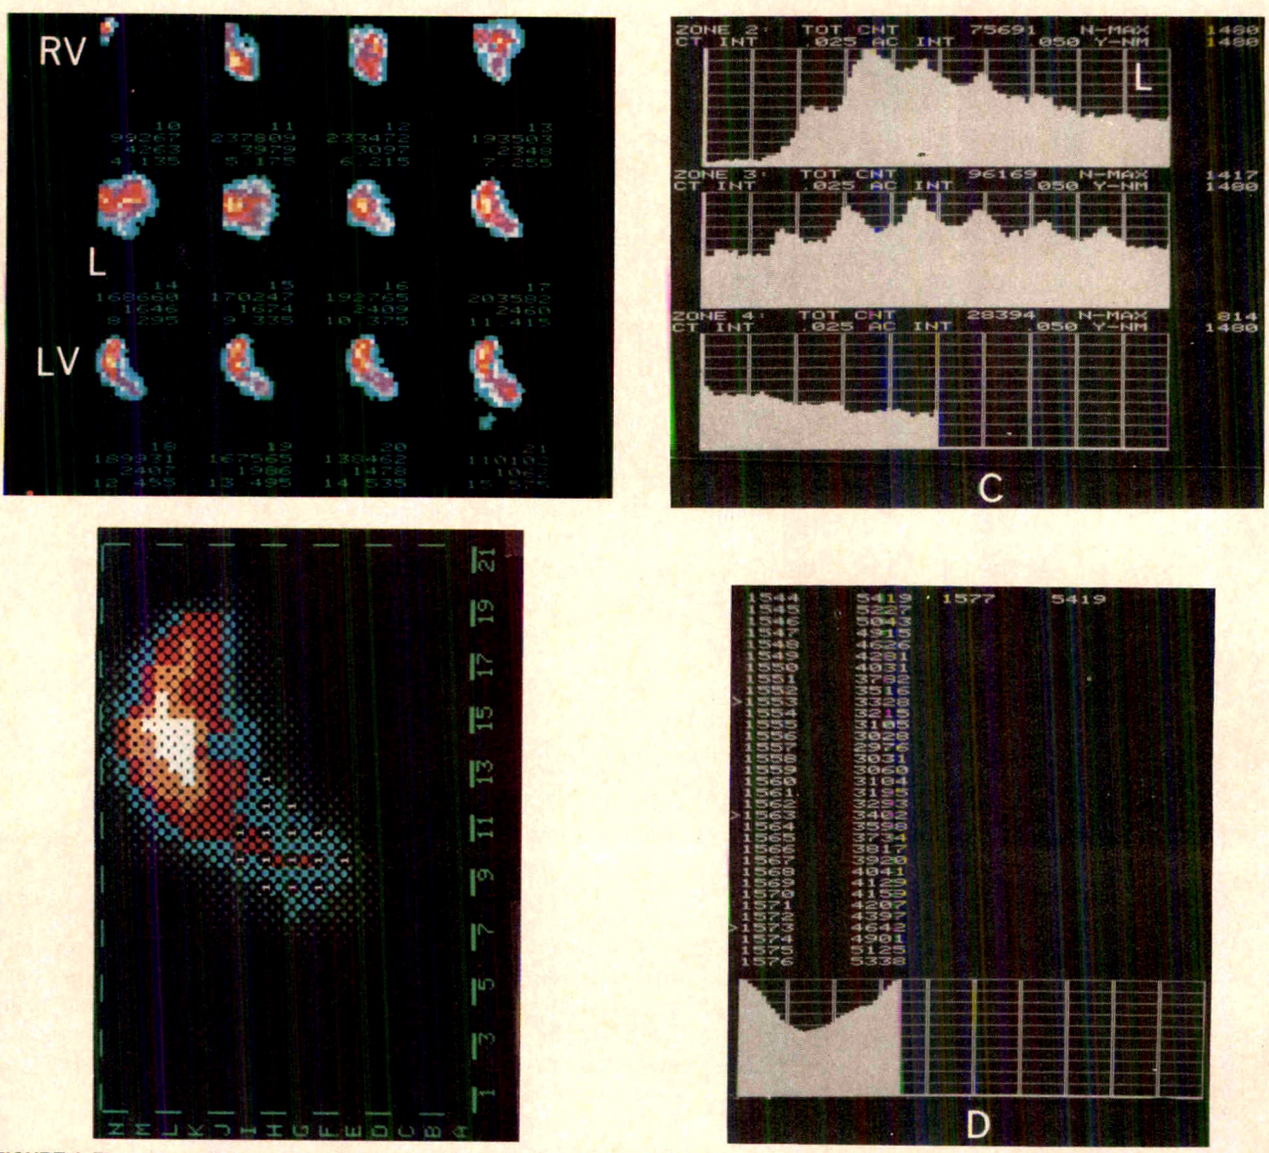

FIGURE 1. First pass technique. **Upper left,** series of images each composed of 1 second of data illustrating first pass transit of a bolus of technetium sequentially through the right ventricle (RV), lungs (L) and left ventricle (LV). Data codes from top to bottom beneath each picture are (1) record number; (2) total counts; (3) maximal number of counts seen by any single crystal; (4) start time in seconds after initiation of computer. **Lower left,** zone grid with preliminary flagging of the left ventricle. **Upper right,** a time-activity curve is then generated. As depicted in the time-activity histogram, the initial peaks and valleys (**top panel**) reflect anatomic overlap between the right and left ventricles. As a result of this overlap, the flags over the left ventricle "see" counts from the right ventricle. However, as the bolus passes through the lung fields (L), a plateau appears. This is followed (**middle panel**) by appearance of the isotope in the left ventricle and the characteristic high-frequency oscillations representing end-diastole (peak) and end-systole (valley). **Lower right,** time-activity curve after background subtraction. The calculated ejection fraction is 45 percent. Although this is strikingly similar to a left ventricular volume curve, considerable difficulties are inherent in determining absolute left ventricular volume from such data (see text).

the bolus modulation that occurs in the chamber of interest, for example, the left ventricle. It can be seen from this curve that there are differences from end-diastole to end-systole that reflect stroke counts. Stroke counts can be divided by end-diastolic counts, after appropriate background correction (see later), to determine ejection fraction (Fig. 1, lower right). Further computer analysis using summed series of beats, usually three to eight, provides a representative cycle that can be played in cine format for qualitative evaluation of wall motion. In addition, a computer-derived series of frames including end-diastole, end-systole, stroke volume and superimposed end-diastolic and end-systolic perimeters can be generated to evaluate wall motion further.

Gated Equilibrium Studies

Limitations in count density attainable during the first pass of an isotope with a single crystal camera and the need to obtain a count density adequate to determine accurately ejection fraction and wall motion led to the development of gated equilibrium radionuclide angiography. The need to count for several minutes requires that the isotope remain fixed within the vascular space. This is accomplished by several agents, the most common being technetium 99m-labeled human serum albumin or in vitro or in vivo labeling of red blood cells.[15]

After time is allowed for equilibration of isotope, the accumulation of counts is synchronized in relation to the portion of the cardiac cycle by using the R wave of the electrocardiogram as a physiologic marker. With current computers the R-R interval can be divided into as many as 100 equal divisions with the appropriate components of the R-R interval added by computer. Studies indicate that at rest, frame durations of 40 to 50 ms have been found adequate[16,17]; during exercise, shorter frame durations of 20 ms are preferred for analysis of other variables, such as ejection and peak filling rate.[17] Most systems require 6 or more minutes to obtain adequate counts for analysis of both ejection fraction and wall motion. Recent studies utilizing a high sensitivity collimator have found that a 2 minute counting interval is adequate for both ejection fraction[18] and wall motion,[19] although there is some loss of edge detection. Derived data are then computer-processed to determine the variables of left ventricular contraction as with first pass data.

Comparison of First Pass and Gated Equilibrium Techniques

Each of these techniques possesses characteristic advantages and disadvantages. With a first pass study, data collection is complete in the time it takes for a single transit, usually less than 30 seconds for most patients. This is of particular significance during interventions such as exercise in which a steady state is necessary. In addition, the sequential arrival of isotope in the right ventricle, lungs and left ventricle with resultant temporal separation permits selection of optimal views of the chambers, which otherwise would be limited by anatomic overlap (see later). Analysis of lung flow is also possible to determine the presence or absence of intracardiac shunts. However, this technique requires a system with high count characteristics and is dependent on obtaining a good bolus injection, which may at times be difficult or impossible, as in severe pulmonary hypertension or in the presence of severe tricuspid insufficiency. Moreover, each study requires a separate injection, thereby limiting the number of studies to three or rarely four injections because of cumulative radiation dose effect. In contrast, the gated equilibrium technique, with its single injection, permits repeat studies either in different projections or to assess the effect of an intervention. In addition, the need for bolus injection is eliminated, allowing the use of this technique in situations where a good bolus cannot be obtained.

Problem of arrhythmias: Arrhythmias can significantly affect the ability to perform and analyze either first pass or gated equilibrium studies. With a first pass study, an isolated ectopic beat that fortuitously occurs during the left ventricular phase may limit the number of beats available for analysis sufficient to require repetition of the study. In contrast, in gated equilibrium studies such occasional beats will be either eliminated by the computer or, if included, will have little effect in view of the large number of beats accumulated in the overall study.

Persistent or severe arrhythmias, such as atrial fibrillation or bigeminy, result in significant changes in left ventricular performance due to variations in the R-R interval. Thus, in such patients, the result obtained from either technique will depend on the R-R interval selected, longer R-R intervals being associated with improved ejection fraction. Wall motion would similarly depend on which beats were analyzed or the acceptance window (R-R interval) selected with the gated equilibrium technique.

Ejection Fraction

Methodologic Considerations

Ejection fraction has been determined using area-length methods[8,20,21] similar to those utilized for contrast ventriculography or count-based methods intrinsically applicable to radionuclide angiography.[13,14,22–28] Whereas area-length calculations require accurate determination of end-diastole and end-systole, this method largely avoids problems of background (see later) and can be used with either first pass or equilibrium studies. However, as with contrast ventriculography, area-length calculations assume that the left ventricle conforms to an ellipsoid of revolution,[29] which limits its accuracy, particularly in the presence of regional asynergy, which is usually present in coronary heart disease. Moreover, overlapping of structures, such as the left atrium and aorta, can make difficult the accurate edge delineation of left ventricular end-diastolic and end-systolic silhouettes.

Count-based technique: These limitations have led to the use of a computer-derived plot of change in counts from end-diastole to end-systole against time as the more commonly utilized approach to determine ejection fraction. The major advantage of this approach

is the relative independence of the time-activity curve from geometric assumptions inherent in the area-length technique. However, it should be noted that geometric assumptions are not completely eliminated. In particular, care must be taken in assigning the appropriate end-diastolic region of interest. In addition, areas of left ventricle more distant from the face of the scintillation camera will contribute fewer counts due to absorption and scatter of the gamma radiation by blood and soft tissue.

Background activity: The major limitation of the count-based technique involves appropriate correction for background activity. Background activity in a first pass or a gated equilibrium study results primarily from counts arising from outside the left ventricular chamber. In the first pass method, background activity resides primarily in the lung fields and left atrium; with the equilibrium technique, isotope is also present in the right heart chambers. As seen in equation $(ED_c - B_c) - (ES_c - B_c)/(ED_c - B_c)$, where ED_c = end-diastolic counts, ES_c = end-systolic counts and B_c = background activity, it is apparent that if one assumes that background activity is stable from end-diastole to end-systole, stroke count is not affected by background. However, because end-diastole must be corrected for background in the denominator, an accurate determination of background activity is essential in order to avoid varying degrees of underestimation of ejection fraction. Despite these limitations, use of change in counts appears to be the most appropriate radionuclide angiographic method for determining ejection fraction both for first pass and equilibrium radionuclide angiography.

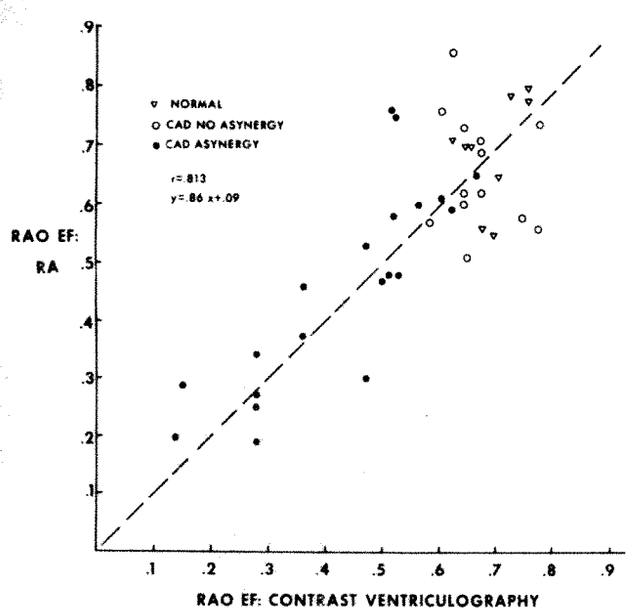

FIGURE 2. Relation between ejection fraction (EF) determined with radionuclide angiography (RA) and contrast ventriculography in 42 patients. Radionuclide angiographic ejection fraction was determined using a count-based technique and a spatial background correction individually selected for each patient on the basis of analysis of the time-activity curve as well as correction for lung washout. CAD = coronary artery disease; RAO = right anterior oblique projection.

Numerous approaches to determining background activity have been utilized.[30] These have involved delineating (i) a "horseshoe"-like area immediately surrounding the left ventricle, (ii) a small zone in a lateral aspect, (iii) a zone demarcated by the difference in end-diastole and end-systole in gated equilibrium techniques,[30] (iv) a phase selected by analysis of the time-activity that precedes arrival of radionuclide in the left ventricle due to temporal separation attained in the first pass technique,[25] (v) a flat background subtraction based on correlations with contrast ventriculography[14] or (vi) a combination of a spatial correction based on analysis of the time-activity curve and, in addition, a correction for lung washout (Fig. 2).

Correlations With Results of Contrast Ventriculography

Several studies incorporating a wide spectrum of patients have correlated ejection fraction obtained by radionuclide angiographic techniques and that found on contrast ventriculography. When gated equilibrium studies were used, ejection fraction determined by the area-length method has shown correlation coefficients from 0.87[20] to 0.93.[21] Others,[13,22,23] using the computer-generated time-activity curve method, have found r values of 0.84 and 0.93. In a series of 30 patients, Folland et al.[31] showed that ejection fraction derived from changes in counts was superior (r = 0.84) to that obtained by the area-length method (r = 0.73). Burow et al.[23] also found that computer-derived techniques were superior to manual approaches. In addition, preliminary data using gated equilibrium studies have indicated that data acquisition for 2 minutes is adequate for accurately determining ejection fraction.[18,32] First pass techniques have also shown good r values from 0.8 to 0.95.[13,14,24–28] Examination of the regression plots reveals, however, that there is a tendency to underestimate higher ejection fractions and to overestimate lower ejection fractions, which must be considered when interpreting a radionuclide-determined ejection fraction.

Folland et al.[31] compared first pass and gated equilibrium methods with contrast ventriculography in the same group of patients. Ejection fraction determined by first pass had an r = 0.86 and that seen on equilibrium studies had an r of 0.84 with contrast ventriculography. Similarly, Wackers et al.[13] and Pfisterer et al.[33] found high correlations between first pass and gated equilibrium studies. In addition, Pfisterer et al. compared first pass and gated equilibrium determination of ejection fraction during exercise and found a correlation of 0.96. When radionuclide angiography was used, reproducibility of ejection fraction measurements on separate days has been found to be good. Marshall et al.[12] found an average variation of 4.4 percent by first pass technique, whereas Wackers et al.[13] found an average variation of 4.3 percent by gated equilibrium methods. These findings are similar to those observed with contrast ventriculography.[34] However, it was also observed that if the initial ejection fraction was in the normal range, greater variability was seen.[12,13] This has important implications when assessing the effect of interventions such as exercise on ejection fraction. It is

of particular interest that Pfisterer et al.[33] has found the response of ejection fraction to exercise in the supine position to be replicable. Thus, despite the potential methodologic limitations, impressive correlations have been obtained.

Left ventricular volumes: Two basic approaches have been utilized to determine end-diastolic and end-systolic volume and thus stroke volume and cardiac output from radionuclide angiographic data. The first and most direct approach is essentially similar to the area-length method for determining ejection fraction (see earlier) and is highly dependent on spatial separation of chambers and accurate edge detection. A modification of this approach uses the ejection fraction determined from the time-activity curve and end-diastolic volume determined by the area-length method to derive stroke volume.[26] The latter reduces to some degree problems in assessing end-systolic volume by geometric assumptions. An alternative approach is based on the use of indicator-dilution theory, which states that if the concentration of an indicator, such as a radionuclide, and the administered dose are known, the volume of distribution, in this case the left ventricle, can be determined. In applying this approach to radionuclide angiography, the counts at end-diastole and end-systole are taken to reflect the concentration in the left ventricle.[35,36] However, correction for administered dose and its volume of distribution is required. This can be obtained by calculating plasma volume[35] using radiolabeled albumin. In addition to the need for this sampling for plasma volume, other potential difficulties are apparent. As with determination of ejection fraction, background as well as differing degrees of attenuation of gamma radiation must be considered. Thus, while radionuclide angiography offers a potentially useful approach and a means of avoiding difficulties inherent in area-length calculations, problems must be overcome prior to its widespread application.

Assessment of Left Ventricular Wall Motion

Although overall variables of left ventricular contraction are of considerable value both prognostically and in assessing the effect of therapy, they may not reflect significant regional abnormalities. This is especially evident in the patient with coronary heart disease, in whom the regional nature of the coronary obstructive disease process often results in a variety of segmental contractile patterns, including normal areas juxtaposed with a discrete aneurysm.[37,38] Depending on the resultant effects on total left ventricular performance, an abnormality in global ejection fraction may or may not be seen. Therefore, for optimal sensitivity and clinical utility, radionuclide angiography should be able to delineate accurately regional wall motion abnormalities, to quantitate the degree of abnormality and to permit a determination to be made of the effect of interventions.

Methodologic Considerations

Several approaches have been utilized to evaluate segmental left ventricular contraction. These include a qualitative reading of the cine and a more quantitative approach using hand- or computer-drawn outlines. In addition, an approach that takes advantage of the ability to quantitate regional count changes using a computer is to determine a regional ejection fraction either as an absolute or relative value.

Optimal projection and rotational factors: Several factors affect the accuracy of assessing segmental left ventricular contraction. The three dimensional nature of the left ventricle ideally requires obtaining multiple views in order to visualize all areas. The right and left anterior oblique and anterior views are most commonly utilized. The right anterior oblique view permits visualization of anterior, apical and inferior zones of the left ventricle. The anterior view has the advantage of better count characteristics compared with the right anterior oblique view; however, foreshortening is present so that the apex and inferior wall are suboptimally visualized. The left anterior oblique projection provides optimal delineation of the septum and posterolateral zones.

Cohn et al.,[4] using contrast ventriculography, found the right anterior oblique projection superior to the left anterior oblique projection in detecting left ventricular asynergy. In 50 patients, both views accurately detected normal contraction in 15 and asynergy in 25. However, in 10 patients, while the left anterior oblique ventriculogram appeared normal, the right anterior oblique ventriculogram revealed segmental asynergy involving the inferior wall in 5, the anterior or apical segment in 3 and both anterior and inferior segments in 2 patients.

In a study in our laboratory, the usefulness of the right anterior oblique and left anterior oblique projections in detecting asynergy in zones of left ventricle supplied by the left anterior descending artery was evaluated. Of 45 patients, 18 had normal wall motion seen in both right anterior (anterior and apical segments) and left anterior oblique (interventricular septum) projections. Twenty-seven patients had asynergy in the left anterior descending arterial distribution, as seen in the right anterior oblique view, nine of these segments were considered normal in the left anterior oblique view. In addition, in the left anterior oblique view, the overlap of the inferior wall and apex as well as the anterior wall and septum further interfered with clear delineation of these areas. This has particular significance in assessment of a ventricular aneurysm, where a clear delineation of each zone is necessary.

Anatomic overlap of cardiac chambers: In the first pass technique, the time required for isotope to pass through the lung fields and into the left ventricle results in a *temporal separation* so that during the left ventricular phase, isotope is no longer present in the right ventricle (Fig. 1). This, to a considerable extent, eliminates the problem of anatomic overlap of right and left ventricular chambers in the right anterior oblique view. However, to the degree that the left atrium and aorta overlap the left ventricle, some interference in the inferobasal and anterobasal segments is still possible. In contrast, in gated equilibrium radionuclide angiography, isotope is present simultaneously in the right and left ventricles without a temporal separation between chambers. Therefore, the left anterior oblique view,

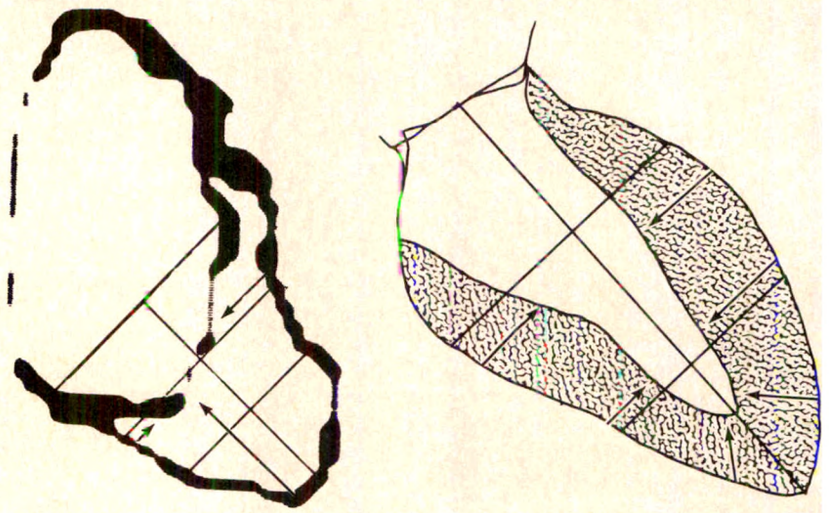

FIGURE 3. Normal ventricular wall motion. **Left,** superimposed radionuclide angiographically derived end-diastolic and end-systolic perimeters showing normal left ventricular segmental wall motion. **Right,** superimposed outline of diastolic and systolic phases of left ventricular contraction based on contrast ventriculography in the same patient (reproduced by permission, from Bodenheimer et al.[14]). **Arrows** show movement from end-diastole to end-systole.

often modified with a caudad tilt to permit anatomic separation of these two chambers, is commonly used with this technique.

Accurate edge detection: Edge detection is fundamental to any assessment of wall motion. In contrast ventriculography, the use of selective injections into the left ventricle markedly enhances edge detection by avoiding overlap of opacified chambers. On the other hand, in radionuclide angiography, the presence of isotope in cardiac and noncardiac structures that overlap the chamber of interest (that is, the left ventricle) interferes with clear delineation of its wall motion. The higher this background activity, the less accurate is edge detection. It has been estimated that during first pass of an isotope through the heart, background activity constitutes 35 percent of the total counts,[12] whereas with the gated equilibrium technique this averages 72 percent.[22] Further interfering with edge detection is uncertainty as to the effect of rotation during cardiac contraction. Thus, view selection and technique are important considerations in performance of radionuclide angiography.

Clinical Applications

Detection of discrete versus diffuse asynergy: One of the earliest uses of radionuclide angiography was to categorize patients with a history of myocardial infarction and congestive heart failure into those with diffuse asynergy and those with a discrete aneurysm amenable to surgical resection.[8,9,20] Rigo et al.,[20] using the gated equilibrium technique and a right anterior oblique projection, accurately detected 11 of 13 patients with a discrete aneurysm and 9 of 9 with diffuse left ventricular involvement. Dymond et al.,[28] using a first pass technique in 18 patients with an old anterior myocardial infarction, were able to distinguish 14 patients with a discrete aneurysm from 4 with diffuse hypokinesia. Other studies have similarly found a good correlation between wall motion determined by either gated equilibrium[21] or first pass methods.[12,14,25]

Determination of location and severity of asynergy: Several methods have been employed to quantitate asynergy. Inaccuracies are inherent in most of these[4,39] and apply to both contrast and radionuclide angiography. Most are related to motion of the heart as a whole, causing difficulties in appropriately diagnosing end-diastole and end-systole.

An early approach to quantitating radionuclide studies involved hand-drawn tracings of end-diastole and end-systole with analyses similar to those used in contrast ventriculography.[8,9] Studies in our laboratory[14] have used computer-superimposed images of end-diastole and end-systole, which are analyzed using a hemiaxial approach (Fig. 3 and 4).

In this technique, the computer-derived images of end-diastole and end-systole are each individually processed by the computer. Because each image is spatially fixed according to the position of the heart at that instant, the addition of the end-diastolic and end-systolic image represents their spatial location. We have *not* attempted to correct for rotation using this technique.

With this method, we have been able to separate normal from abnormal segmental motion in different areas of the left ventricle and to delineate a normal range. It became apparent, however, that the extent of contraction was different as seen on contrast ventriculography and radionuclide angiography (Table I). Thus, for example, motion of the normal apex was found to be far greater with radionuclide angiography[14] compared with contrast ventriculography, emphasizing the need to identify the normal contraction pattern for radionuclide angiography. Once this range is defined, an excellent relation exists between the delineation of normal segmental motion by radionuclide angiography and that found on contrast ventriculography. In a series

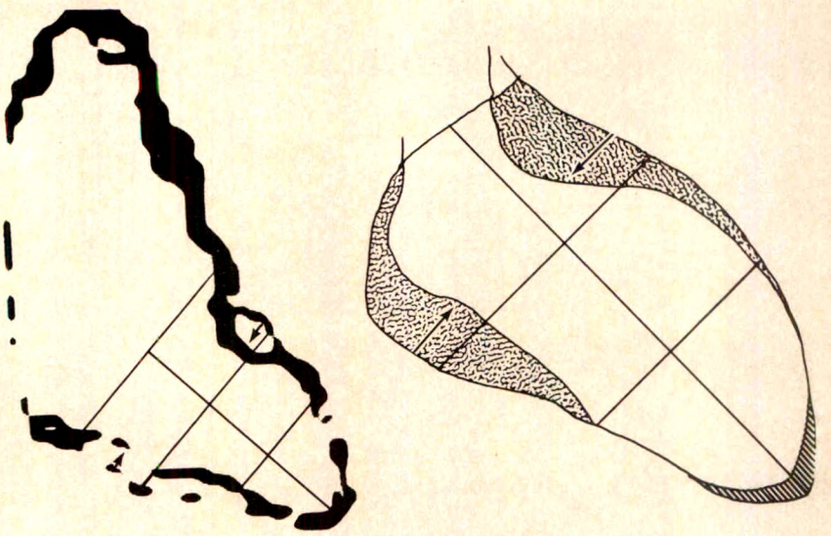

FIGURE 4. Ventricular asynergy. Comparison of radionuclide angiographic end-diastolic and end-systolic perimeters in the right anterior oblique view (**left**) with contrast ventriculographic wall motion analysis (**right**). Segmental akinesia of the anterior segment and dyskinesia of the apical segment with preservation of inferior and anterolateral wall motion (**arrows**) are clearly depicted by both techniques (reproduced by permission, from Bodenheimer et al.[14]). **Arrows** show wall motion from end-diastole to end-systole.

of 34 patients with normal findings as assessed with cardiac catheterization results of radionuclide angiography were normal in 94 percent.[40]

The presence and severity of asynergy depicted on radionuclide angiography also correlated well with those findings on contrast ventriculography. Asynergy in the anterior or inferior zones corresponded closely with contraction abnormalities seen on the contrast ventriculogram in our studies as well as in others.[12,21,25] Rarely, however, a small discrete area of apical asynergy visualized on contrast ventriculography will not be detected with radionuclide angiography. We have noted this in three patients among several hundred patients in our experience. However, to date all large anterior and apical akinetic and dyskinetic zones have been well demarcated with respect to both location and severity (Fig. 4).

Another region that may be suboptimally seen is the inferior segment. Although an excellent correlation between contrast ventriculography and radionuclide angiography was seen in the majority of patients, some patients with distinct inferior wall akinesia seen on contrast ventriculography will show normal motion in the radionuclide angiogram. Although the reason for this difference is unclear, it may relate to the presence of simultaneous mitral regurgitation (as was seen in one patient) or rotational motion of the heart, which may give the impression of motion that cannot be accurately delineated with the less rapid framing of radionuclide angiography. It is also conceivable that counts arising from the inferior wall are attenuated compared with those of the anterior and apical walls.

An alternate form of analysis is to determine regional ejection fraction using a count-based method similar to that employed for global ejection fraction.[41–43] In this technique, the change in counts for a given area of the left ventricle can be assessed by computer and used to quantitate the contribution of different areas of left ventricle to ejection fraction. This technique has been utilized in our laboratory to evaluate response of left ventricular contraction to exercise. We have found that a 25 percent difference in counts between anterior and inferior areas represents an abnormality and is represented by a 4 color shift on our 16 color scale. This method has its inherent limitations, including the needs for accurate background subtraction and accurate edge detection as well as the inability to evaluate very small areas of left ventricle because of limitations in resolution and counts.

Intervention radionuclide angiography: In recent years, the concept of left ventricular contraction as a dynamic process has gained increasing acceptance.[38] Several studies have shown that at times asynergy can be elicited or worsened by exercise[44–47] or other ma-

TABLE I

Assessment of Severity of Segmental Asynergy by Radionuclide Angiography (mean ± SEM)

Contrast Angiography	Radionuclide Angiography (% shortening)		
	Anterior	Apical	Inferior
Normal (8 patients) (25 percent or greater hemiaxis shortening)	70.1 ± 9.6	48.3 ± 7.3	62.2 ± 6.9
Asynergy (22 patients)			
Hypokinesia (25 percent or less hemiaxis shortening)	20.1 ± 5.2 (7)*†	11 (1)	17.2 ± 6.5 (5)†
Akinesia/dyskinesia (5 percent or less hemiaxis shortening)	4.0 ± 4.0 (4)‡	10.4 ± 7.3 (5)†	7.5 ± 4.1 (8)

* Figures in parentheses indicate number of segments.
† $p < 0.005$ compared with normal values.
‡ $p < 0.05$ compared with hypokinetic segment.
SEM = standard error of the mean.

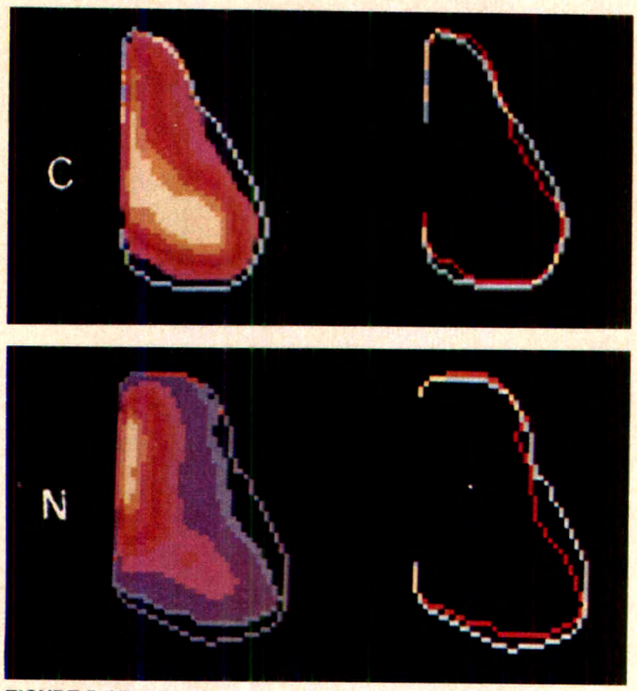

FIGURE 5. Nitroglycerin radionuclear angiography. Computer-superimposed end-systolic image with the end-diastolic perimeter (**left**) and computer-superimposed end-diastolic (white) and end-systolic (red) perimeters (**right**) before (C) and after nitroglycerin (N). A large zone of anterior hypokinesis and apical akinesis is seen in the control imaging (C). After nitroglycerin (N), marked improvement of contraction of the anterior zone is seen with persistence of a small area of apical akinesia. Color code includes 16 colors from black through green, blue, red, yellow and white. Each color represents a 6.25 percent range. The colors are distributed normalized to the crystal with the greatest number of counts in that given frame of data.

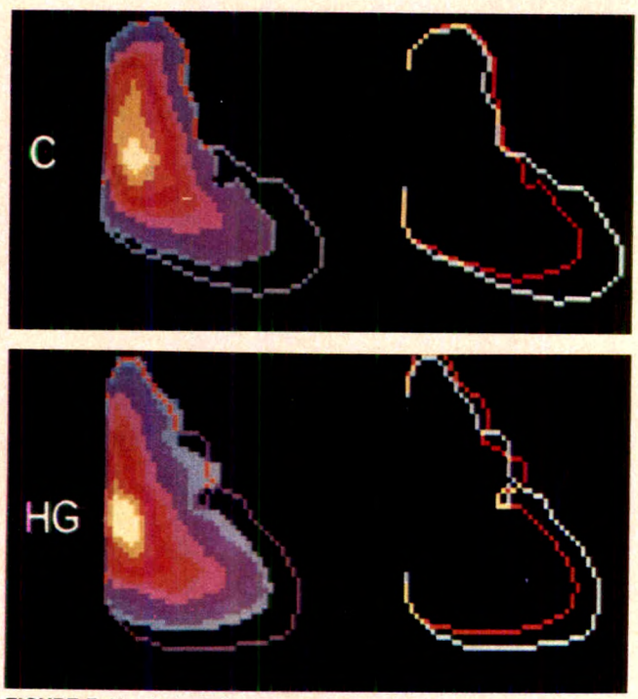

FIGURE 7. Handgrip radionuclear angiography (format similar to that of Figure 5). A normal contraction pattern is seen at rest (C); however, a second angiogram during handgrip (HG) exercise shows anterior and apical asynergy (hypokinesia).

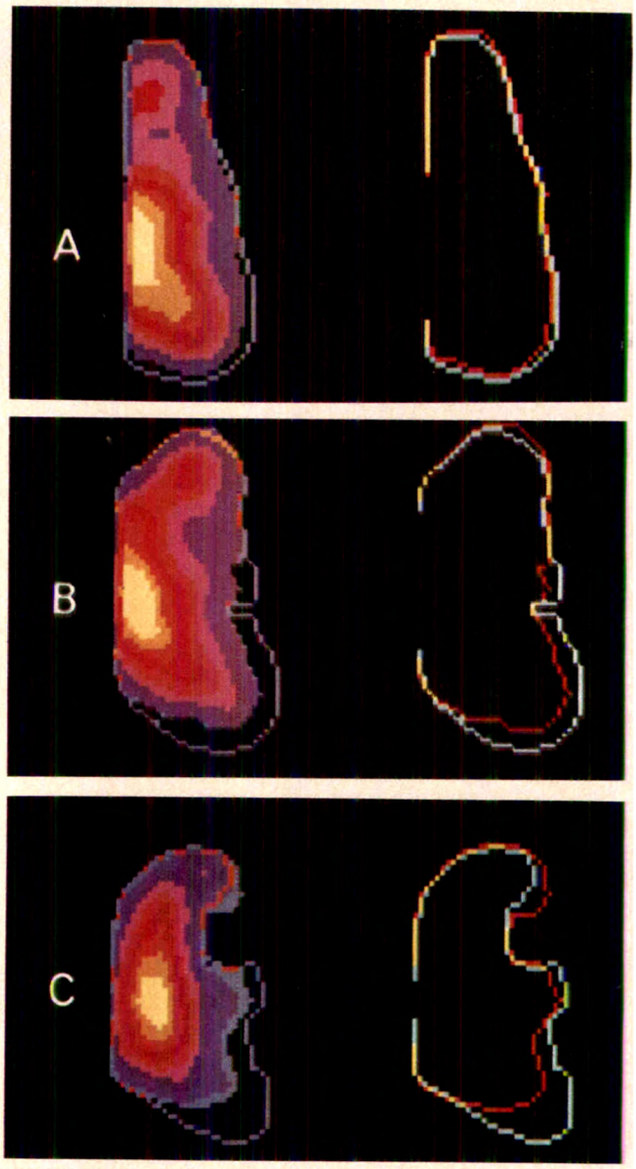

FIGURE 6. Nitroglycerin radionuclear angiography (format similar to that in Figure 5) in a patient with severe angina referred for evaluation after having been rejected for coronary arterial bypass grafting because of poor left ventricular function including severe anterior and inferior asynergy at catheterization. **A,** control angiogram reveals asynergy. **B,** after administration of nitroglycerin there is marked improvement of motion in both anterior and inferior zones. **C,** Follow-up study after coronary bypass reveals normalization of anterior and inferior contraction.

neuvers[48] or, conversely, reversed by nitroglycerin[49] or postextrasystolic potentiation.[50,51] These observations have led to the increasing use of intervention ventriculography to delineate more fully the true contraction pattern of the left ventricle.

The approach that has evolved in our laboratory is to assess initially left ventricular contraction at rest. If a contraction abnormality is present, a nitroglycerin radionuclide angiogram is obtained. In contrast, if wall motion appears normal on initial study, radionuclide

angiography during stress is performed. This technique has also been increasingly utilized to assess response of left ventricular contraction in various settings.[52–56]

Assessment of reversible asynergy: In recent years, techniques have been developed to determine whether an abnormally contracting segment of left ventricle is composed of viable, albeit ischemic, cardiac muscle or nonviable or fibrotic tissue.[49,57–59] Studies in our laboratory[49,59] have shown that an abnormal contracting zone that shows improvement after the administration of sublingual nitroglycerin is composed of viable cardiac muscle (Fig. 5). Intraoperative studies[59] utilizing transmural biopsy specimens of the left ventricle and epicardial electrographic recordings have shown that asynergic zones that improved after administration of nitroglycerin were composed of histopathologically normal myocardium. In contrast, zones that did not respond to nitroglycerin consisted substantially of fibrotic tissue. Recent studies[60,61] have confirmed the value of nitroglycerin ventriculography in assessing potential improvement of an asynergic zone.

Recently,[52] radionuclide angiography with nitroglycerin has been used to detect the presence of reversible asynergy. The technique involves recording a baseline radionuclide angiogram followed by administration of sublingual nitroglycerin sufficient to produce a decrease in systolic pressure. A second radionuclide angiogram is then obtained. The control and nitroglycerin radionuclide angiograms can be compared both qualitatively and quantitatively to assess changes in asynergic segmental contraction. Using this approach, we have been able to identify patients who appear to have severe asynergy, yet who have viable myocardium with potential for functional improvement. Figure 6 illustrates radionuclide angiograms in a patient who demonstrated anterior and inferior wall akinesia and who responded to nitroglycerin with resulting improvement of segmental wall contraction. After coronary arterial bypass surgery, contraction of both the anterior and inferior walls was normalized.

Radionuclide angiography at rest and during exercise to detect coronary heart disease: Experimentally, one of the earliest measurable responses to a reduction in coronary blood flow is appearance of a contraction abnormality in the subserved segment of left ventricle. Only later is this followed by the appearance of S-T segment abnormalities. Clinically, 60 to 70 percent of patients with angiographic evidence of coronary artery disease have abnormalities of left ventricular contraction at rest. Presumably, the absence of asynergy in the remaining patients implies adequate oxygen supply at rest. When oxygen demand is sufficiently increased, ischemic dysfunction and asynergy result. This concept led to evaluation with radionuclide angiography of left ventricular contraction both at rest and during exercise to detect coronary heart disease.

Borer and coworkers[62,63] initially described the use of radionuclide determination of ejection fraction and wall motion at rest and during bicycle exercise. They found that the normal response was an increase in ejection fraction. In contrast, patients with coronary heart disease showed a decrease or no significant change in ejection fraction or new wall motion abnormalities, or both. All 47 patients with coronary artery disease exhibited this abnormal response. In a more recent report these investigators[64] found a sensitivity of 95 percent in a series of 63 patients with coronary heart disease. Rerych et al.[26] reported a similar high sensitivity using bicycle exercise and first pass radionuclide angiography in a series of 30 patients with coronary heart disease.

Berger et al.[65] examined the interrelation among changes in ejection fraction, wall motion and ischemic S-T segment responses during bicycle exercise. Overall, they found that 48 of 60 patients with coronary heart disease showed either an abnormal ejection fraction response (decrease or no significant change) or a wall motion abnormality with exercise. Of 30 patients in whom an ischemic response developed as indicated by S-T segment depression, all showed either a decrease or no increase in ejection fraction. Of the remaining 30 patients, in whom an abnormal S-T response did not develop, 15 had normal left ventricular contraction at rest and the stress test had to be discontinued because of fatigue, with only 7 patients demonstrating abnormal left ventricular reserve. The other 15 patients had abnormal left ventricular function at rest; after exercising to fatigue, 11 were found to have abnormal left ventricular reserve despite a negative S-T segment response.

It thus appears that detection of abnormalities in left ventricular contraction at rest or during exercise is of considerable value in diagnosing coronary heart disease. Such abnormalities can be detected prior to the occurrence of S-T segment abnormalities[66] and may be seen in patients with a normal electrocardiogram.[65] However, the interpretation of a normal response to a suboptimal exercise level is currently unclear. Although this procedure clearly represents an improvement in the detection of coronary heart disease in such patients, the disease will not be discovered in a significant number of subjects.[65] Thus, an important aspect of this form of testing is to attain adequate levels of stress.

Isometric handgrip exercise test: The rapid data acquisition possible during first pass radionuclide angiography permits use of alternate forms of stress such as isometric handgrip exercise[41,42] (Fig. 7). Isometric exercise has been demonstrated to induce abnormalities in left ventricular function[46] and has the advantages of ease and rapidity of performance and elimination of motion artifact, because the patient lies supine. In addition, the simplicity of the test results in the successful completion of exercise in essentially all patients we have studied. The major theoretical disadvantage of this form of stress lies in the fact that the increase in myocardial oxygen consumption is less than it is with isotonic exercise.[67] In view of the relatively small changes in ejection fraction induced by handgrip analysis, we analyzed wall motion and a computerized assessment of regional ejection fraction.[42] By means of this approach, coronary heart disease was detected by wall motion analysis in 68 percent of patients and by the regional ejection

fraction method in 91 percent. This was accomplished with a high degree of specificity. Thus, exercise radionuclide angiography provides a promising new approach to assessment of the patient with suspected coronary heart disease.

Assessment of myocardial infarction: In the patient with an acute myocardial infarction, radionuclide angiography can be used to assess the extent and severity of the resultant contraction abnormality as well as overall ventricular function. Rigo et al.[68] evaluated 38 patients with an acute myocardial infarction, 36 of whom showed an akinetic zone ranging from 15 to 59 percent of the left ventricular wall consistent with the electrocardiographic site of infarction. Similarly, Schad[69] demonstrated wall motion abnormalities in the electrocardiographically demarcated site; however, this investigator noted that the asynergy varied in severity.

The ability to evaluate serially patients with an acute myocardial infarction[68,70–73] also allows for a determination of the natural history of the acute infarct zone as well as its responsiveness to interventions. Rigo et al.[68] restudied 20 patients between 1 week and 3 months after an acute infarction and found that 14 patients whose course was uncomplicated or who had clinical improvement during hospitalization showed an improvement in ejection fraction. In contrast, of six patients with severe symptoms and no clinical improvement, ejection fraction remained unchanged. Similarly, Schelbert et al.[70] showed that ejection fraction may either increase or remain unchanged over time, whereas Reduto et al.,[71] in a study of 31 patients with uncomplicated myocardial infarction studied serially, found no significant differences in wall motion or ejection fraction as a function of time.

Using first pass radionuclide angiography, we[73] have studied 23 patients with an acute transmural myocardial infarction. All 23 showed asynergy in the zone corresponding to that seen in the electrocardiogram. Of particular interest was the finding that after administration of sublingual nitroglycerin, improved contraction in the asynergic zone was seen in 20 of 23 patients In contrast, no significant improvement was seen in a separate group of 16 patients with an old infarction.

In a subsequent study,[72] 16 patients with an acute transmural myocardial infarction were serially evaluated within 24 hours of the onset of pain and after 5 to 7 days and after 4 to 6 weeks. Like Reduto et al.,[71] we found no significant change in the asynergic zone among the three studies. However, somewhat surprisingly, after administration of sublingual nitroglycerin, we found improvement in segmental contraction in 12 of 16 patients in the initial study and a somewhat lesser improvement in the majority of patients at 5 to 7 days. Restudy[72] 4 to 6 weeks after infarction showed no significant improvement in contraction of the infarcted area after nitroglycerin administration. Thus, radionuclide angiography provides a useful new means of evaluating the extent and severity of the contraction abnormality resulting from an acute myocardial infarction and the overall ejection fraction and, in addition, of determining the responsiveness of the infarct zone to interventions.

Future Directions and Clinical Implications

The future role of radionuclide angiography will be determined by (1) the definition and refinement of its uses, limitations and relative advantages and disadvantages compared with those of other noninvasive methods, and (2) the development and cost of newer imaging devices (currently a computerized scintillation camera costs approximately $150,000 to $180,000) and radiopharmaceutical agents. On the basis of current technology, although minor modifications will appear, there is urgent need for better delineation of the accuracy of radionuclide angiography compared with other techniques such as two dimensional echocardiography in evaluating left ventricular function at rest and particularly during interventions. In addition, the diagnostic sensitivity and specificity of stress radionuclide angiography in detection of coronary heart disease must be systematically compared with thallium-201 myocardial perfusion imaging to provide guidelines in selecting the appropriate study.[74–77] The optimal stress[78,79] and projection used, the prognostic importance and the utility in screening asymptomatic individuals all require further study. Indeed, it is conceivable that differing modes of stress may be required, depending on the clinical setting.

Newer computer techniques: From a technologic standpoint, the increasing availability of computer capability at relatively low cost and the development of new collimators have led to preliminary work on planar tomography with current generation scintillation cameras and modified computer software.[80] This technique can potentially provide increased reliability in assessing zonal contraction because of improved edge detection, which is partly achieved by reducing problems of background activity. Another approach to assessing zonal contraction relies on computer analysis to dissect out the sequence of contraction of differing areas of myocardium.[81] This approach requires high framing rates with maintenance of good count characteristics, which is currently difficult because of technical limitations. However, this technique may permit detection of asynchronous contraction, thus providing a more sensitive means of detecting contraction abnormalities in a way similar to that used in contrast ventriculography.[29]

Newer imaging devices: Development of solid state imaging devices would effect a major improvement in both count characteristics and resolution resulting in a significant increase in usefulness of these techniques. A newer imaging device, the multiwire proportional chamber, awaits the development of new low-energy isotopes that would permit its use. In general, other improvements in radiopharmaceutical agents would be of value, such as a generator that produces an isotope with a short half-life, with resultant lower background and less radiation burden to the patient.

Clinical implications: The evaluation of current technology and available data permits several clinically relevant conclusions. Radionuclide angiography, by its ability to determine both global and regional left ventricular function, provides a reliable noninvasive means to aid in diagnosis, assess prognosis and guide therapy. In particular, radionuclide angiography is of considerable clinical value for the following: (1) evaluating left ventricular contraction (for example, detection of discrete versus global inoperable asynergy); (2) determining the effect of interventions (for example, detection of reversible asynergy, with its therapeutic implications); and (3) eliciting asynergy or an ejection fraction abnormality, or both. Radionuclide angiography may also prove to be a useful means of assessing the size and course of an acute myocardial infarction. Moreover, its capability of providing serial studies of left ventricular contraction affords a method of assessing both the natural history of and the effect of differing therapies on a wide variety of cardiac diseases.

Acknowledgment

We thank George Hermann, MD, Chairman, Department of Nuclear Medicine, for his helpful review and comments during preparation of this manuscript. We also thank Kathleen McNair and Jeanne Harrison for their secretarial assistance.

Nuclear Cardiology. II. The Role of Myocardial Perfusion Imaging Using Thallium-201 in Diagnosis of Coronary Heart Disease

MONTY M. BODENHEIMER, MD, FACC
VIDYA S. BANKA, MD, FACC
RICHARD H. HELFANT, MD, FACC

Philadelphia, Pennsylvania

Since its introduction, thallium-201 has become the agent of choice in the clinical assessment of relative myocardial perfusion. Extensive evaluation has shown that it is of particular value in the diagnosis of coronary heart disease in patients with baseline S-T segment abnormalities or an inadequate heart rate response resulting in an inconclusive exercise electrocardiographic response. In addition, thallium-201 imaging is of value in the patient with a suspected false positive stress test; however, the definite incidence of false negative studies in patients with coronary heart disease tempers complete reliance on this approach. In the patient with a diagnostic exercise electrocardiographic stress test, thallium-201 provides limited additional information. Moreover, current techniques of analysis do not permit assessment of the number of coronary arteries with obstructive lesions.

In the setting of acute myocardial ischemia, the role of thallium-201 is less clear. In acute myocardial infarction, the significant incidence of false negative responses combined with a multiplicity of potential causes of resting defects including severe but chronic coronary disease or unstable angina limits its diagnostic value.

Thallium-201 myocardial perfusion imaging is currently the most commonly used diagnostic radionuclide procedure in patients with suspected or proved heart disease or myocardial ischemia. Since its introduction as a means of assessing relative myocardial perfusion,[1,2] thallium has been in progressively widespread clinical use and has replaced other agents, including potassium-43, rubidium-81, and cesium-129. This widespread use is based on its relatively favorable radiopharmaceutical characteristics, including its reasonably long shelf life and suitability for imaging with current scintillation cameras,[3] although the cost of the isotope (approximately $100 per patient) is considerable. The purpose of this review is to assess the uses and limitations of thallium-201 perfusion imaging in the diagnosis of the acute and chronic manifestations of coronary heart disease.

Theoretical Considerations

Thallium-201 is a potassium analog with a physical half-life of 73 hours. It is rapidly extracted by normally functioning myocardial cells, most probably by membrane adenosine triphosphatase. Estimated whole body exposure is 70 mrad/mCi[1,2] with a renal dose of 520 mrad/mCi.[2] Although similar to potassium in many regards, significant differences have been reported. Potassium-43 is characterized by a shorter half-life (22 hours), a higher radiation exposure of 700 mrad/mCi[2] and a shorter myocardial half-life, thereby limiting the number of views obtainable. In addition, thallium images provide better definition of experimental myocardial lesions.[4]

Factors affecting myocardial distribution of thallium: To understand better the uses and limitations of thallium in various clinical settings, several factors that affect the myocardial distribution of the isotope in the resting state must be considered. Concentration of thallium is determined by several factors: (1) the amount of isotope delivered by coronary flow, (2) myocardial uptake, and (3) the rate of myocardial isotope efflux.

Experimental studies[5] have shown that initial myocardial extraction of thallium is rapid with a net positive arteriovenous difference lasting for 8 minutes after injection. The arteriovenous difference then becomes negative, indicating a net loss of thallium from the myocardium.[4] Strauss et al.[6] demonstrated that thallium distribution accurately reflects myocardial perfusion in the normal heart as well as in hearts with partial and total coronary occlusion. Similarly, Selwyn et al.[7] in a series of animal studies produced graded reduction in coronary flow and measured myocardial perfusion with thallium-201 and krypton-81m. The presence of ischemia was determined by S-T segment displacement in epicardial electrograms. Reduction in coronary flow sufficient to be detected with krypton but not with thallium was not associated with epicardial S-T segment abnormalities, suggesting that small decreases in flow will not be detected, presumably because of persistence of normal cell membrane function. However, if the reduction in coronary flow resulted in epicardial S-T segment elevation or depression, an abnormality in myocardial perfusion was detectable with thallium.[7] In addition, when myocardial creatine kinase was determined as an index of myocardial ischemia, a good relation was found with thallium scans. However, experimental data[8] show that thallium is *not* released from ischemic myocardium.

Nevertheless, although thallium content is reduced in an area of experimental infarction, it may still be as high as 86 percent in the nonischemic zone.[9] This relatively small difference would significantly affect the ability to detect a perfusion deficit with currently available imaging systems. Further complexities are introduced by evidence that thallium distribution is not fixed. Thus, serial sampling or repeated imaging of myocardium reveals that redistribution of thallium is not infrequent.[10]

With regard to the effect of coronary occlusion and reperfusion on myocardial thallium distribution, Pohost et al.[10] found that myocardial blood flow measured with thallium correlated well with radioactive microsphere measurement ($r = 0.95$); moreover, after 20 minutes of coronary reperfusion, thallium activity increased markedly, reflecting the enhanced myocardial flow and not the original distribution. Reperfusion had no significant effect on microsphere distribution. In a study by Schwartz et al.[6] initial thallium distribution in an ischemic area was 5.5 percent of that in the nonischemic myocardium, whereas 5 minutes after reperfusion, thallium activity increased to 44 percent and further to 69 percent at 15 minutes, reaching a plateau at this level during the remaining period of observation. The mechanism underlying this redistribution appears to be a combination of uptake of thallium from the blood pool by the previously ischemic zone and a loss from the nonischemic area of isotope, which has an estimated biologic half-life of 4.5 to 7 hours.[4,10] The resulting image thus represents the net effect of thallium uptake by the previously ischemic zone and loss from the nonischemic zone.[11] An additional consideration is the possible contribution of collateral flow.

It appears, however, that thallium uptake depends on the integrity of myocardial cell function (in particular, that of membrane adenosine triphosphatase). Thus, during administration of thallium, a transient loss of cell function results in a perfusion defect, as, for example, one caused experimentally by occlusion or clinically by exercise-induced or resting ischemia. Upon relief of the ischemia, cell function is restored and the defect is no longer seen on later scans. On the other hand, if the failure of uptake is a result of irreversible injury or scar, then the defect will persist. Although these data emphasize the effect of cell ischemia on extraction of thallium-201, Gewirtz et al.[8] showed experimentally that thallium is not lost more rapidly from a zone made ischemic *after* administration of thallium.

The size of the involved area of myocardium, whether comprised of ischemic tissue or scar, or both, will determine the presence or absence of a defect in the thallium image. Experimental studies by Mueller et al.[12] showed that a minimum of 5 g of myocardium must be involved in abnormal thallium uptake for a defect to be visualized on a thallium image. Clinically, Niess et al.[13] demonstrated that generally 6 percent or more of the left ventricle must be involved to be detected on a thallium study at rest. In addition, anterior defects are more easily and accurately detected than either inferior or posterolateral defects.

Technical Considerations

Thallium imaging after exercise: The utility of thallium-201 imaging in detecting coronary heart disease has been extensively evaluated.[14–21] Although thallium imaging at rest has occasionally been used,[22] its sensitivity is markedly enhanced when performed with exercise, as initially demonstrated by Zaret et al.[23] using potassium-43. The technique currently employed involves a single standard symptom-limited maximal exercise test with intravenous administration of 1.5 to 2.0 mCi of thallium-201 at peak exercise, which is then continued for an additional 60 seconds. The electrocardiogram and blood pressure are recorded as for routine exercise testing both during and after exercise. Within 5 to 10 minutes of completion of exercise imaging is begun in multiple views that include anterior and left anterior oblique projections. The need to begin imaging rapidly requires that exercise be performed near the detector.

Thallium combined with dipyridamole vasodilation: Whereas most studies have employed the technique just described, another approach has been to induce pharmacologically changes in coronary blood flow.[24–26] Experimental studies have shown that phar-

macologic vasodilation can be utilized to detect areas of decreased perfusion.[24,25] Presumably the relatively high flow induced by vasodilation in normal areas coupled with a lesser amount of thallium delivered to the area subserved by an obstructed vessel will result in a disparity in relative flow and thus a perfusion defect. Using this approach, Albro et al.[26] compared resting and exercise thallium imaging with thallium combined with dipyridamole, a potent coronary vasodilator. Sensitivity was identical for exercise thallium and thallium imaging during administration of dipyridamole (67 percent). Similarly, in 11 normal patients, one false positive result occurred with each approach. Thus, this technique may be of potential value in the patient who cannot perform adequate exercise.

Tomographic imaging: Vogel et al.[27] recently reported the use of a seven pinhole collimator that permits tomographic imaging and gives the theoretical advantage of reducing superposition of cardiac walls, thereby providing better segmental analysis. This type of collimator, although originally designed for wide-field-of-view Anger cameras, is now being adapted to conventional Anger cameras. The images can then be evaluated qualitatively and quantitatively using currently available computers that can be reprogrammed to facilitate this type of study. In an initial comparison with conventional imaging, tomographic imaging showed an improvement in sensitivity with similar specificity for coronary heart disease. However, a preliminary assessment of its ability to quantitate the number of obstructed coronary arteries was less promising.[28] Thus, further work will be required to determine the optimal use of this device.

Computer-assisted analysis of thallium images: A recent cooperative multicenter study indicates that a wide variety of current generation imaging devices are equally capable of providing high quality thallium images.[18] Interobserver variability has ranged from 14 to 21 percent[14,15] for analysis of resting and exercise images. However, computer-assisted analysis of the thallium images is being increasingly used to obtain more objective diagnostic information, to improve detection and to compare studies (Fig. 1). Although varying to some extent depending on the system utilized, all computer methods rely on obtaining a count pattern representative of a given area of the heart. This permits establishing a normal range, which can then be used to assess significance of count differences between zones, allowing consistent interpretation. Berger et al.[29] showed that such computer-processed images were essential for diagnosis in 20 percent of patients and enhanced visual certainty in an additional 20 percent. A quantitative approach was of particular value in diagnosing inferior and nontransmural myocardial infarctions.[29] Other investigators[19–21,30,31] similarly found quantitative techniques to be of value. However, this count pattern does *not* represent absolute myocardial flow. Rather, the count distribution (with or without background subtraction) provides a measure of the relative distribution of counts and thus only indirectly allows relative myocardial blood flow to be estimated. This has important implications for the detection of multivessel coronary heart disease (see later).

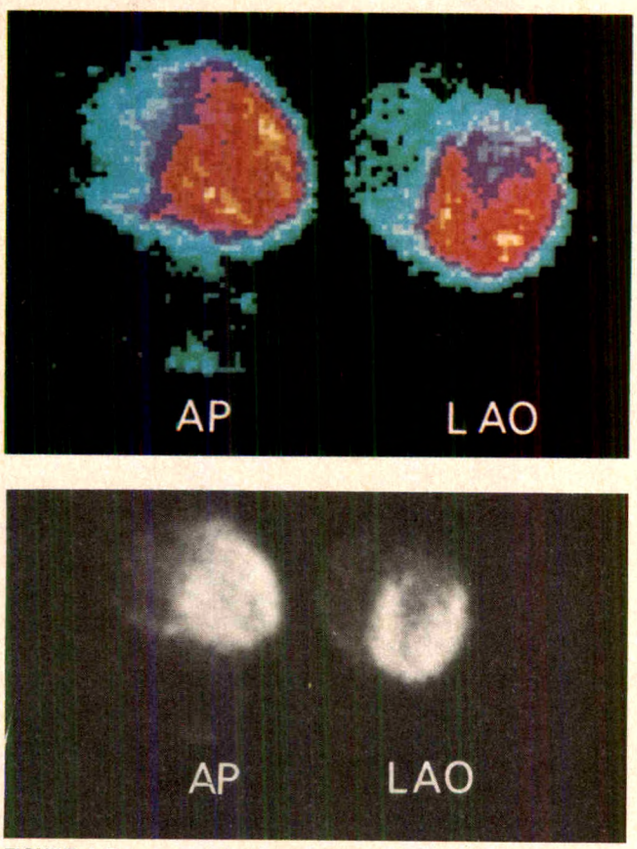

FIGURE 1. Top, normal thallium-201 myocardial perfusion scan in the anterior (AP) and left anterior oblique (LAO) projections obtained immediately after exercise. Color scale ranges from black (lowest level) through shades of green, blue, purple, red, yellow and white representing crystals with the greatest number of counts. **Top,** color images are displayed as a 16 color isocount, smoothed image after background subtraction of 39 percent determined by use of a count profile. **Bottom,** black and white images are similarly displayed smoothed after a background subtraction of 39 percent.

Chronic Coronary Heart Disease

A patient with chest pain presents the physician with the diagnostic problem of deciding whether the cause is coronary heart disease and, if so, its severity. Although at times the patient's history may be conclusive, it is often equivocal. Similarly, although the resting or exercise electrocardiograms are of value they have significant limitations in sensitivity and specificity. Moreover, neither clinical nor electrocardiographic findings are helpful in determining the number of coronary arteries with obstructive lesions and the associated prognostic and therapeutic implications. Most of the studies assessing the clinical usefulness of stress thallium imaging in this setting have compared it with stress electrocardiography. As indicated later, it has been found that thallium imaging generally is a somewhat more accurate study than the stress electrocardiogram and has particular usefulness in certain patient subsets.

Detection of Chronic Coronary Heart Disease: Comparison of Stress Electrocardiography and Stress Thallium Imaging

Most of the studies evaluating stress thallium imaging have compared it with simultaneously performed electrocardiography in patients undergoing coronary arteriography (Table I). The largest report to date is a multicenter cooperative study[18] involving 190 patients, of whom 42 had angiographically nonobstructive coronary lesions (less than 50 percent narrowing) and 148 had obstructive coronary disease. Of the patients with coronary heart disease, 47 percent had S-T segment depression alone, whereas pathologic Q waves with or without S-T segment depression were present in 73 percent. Thallium-201 perfusion abnormalities at rest or during exercise were seen in 76 percent. The relative sensitivities of electrocardiographic criteria (Q or S-T segment abnormalities, or both) and thallium-201 imaging were not significantly different. Similarly, the specificity of resting and stress electrocardiography was 86 percent and that of thallium-201 imaging was 88 percent. Combining the electrocardiographic Q wave and S-T segment abnormalities with findings on thallium-201 imaging, however, increased the sensitivity to 91 percent. Although this was statistically significant compared with results of either electrocardiography or thallium-201 imaging alone, specificity decreased to 81 percent (not significant). As seen in Table I, several centers have individually reported relatively similar data.

Effect of exercise level on sensitivity: Several investigators have examined the possibility that thallium-201 imaging would be of particular value in certain subgroups of patients. McLaughlin et al.[32] demonstrated that although thallium-201 imaging was reproducible in 91 percent of patients, in a group of 12 patients subjected to two levels of exercise, only 53 percent showed defects at light exercise compared with maximal exercise. McCarthy et al.[19] similarly evaluated the stress electrocardiogram and thallium-201 studies in relationship to *degree of exercise* attained.[19] Overall, these investigators found that thallium-201 perfusion imaging is both more sensitive (85 versus 64 percent) and more specific (84 versus 71 percent) than exercise electrocardiography. The data were then analyzed with regard to the adequacy of the stress. Patients with coronary heart disease who exercised to 85 percent or more of maximal predicted heart rate or significant (1 mm or greater) S-T segment depression had an 88 percent incidence rate of such S-T segment abnormalities. Similarly, 87 percent had thallium-201 perfusion abnormalities. Of 20 normal patients with a stress test defined as adequate, specificity was 85 percent for both the electrocardiogram and the thallium-201 image. Combining S-T segment abnormalities and findings on thallium-201 imaging yielded a sensitivity of 97 percent; however, specificity decreased to 70 percent. In contrast, of 32 patients with coronary heart disease and nondiagnostic stress tests (that is, an inadequate heart rate response or an uninterpretable electrocardiogram), thallium-201 imaging detected perfusion abnormalities in 81 percent with a specificity of 69 percent.

We have found similar results in 117 patients studied in our laboratory. Overall, of 84 patients with coronary heart disease, S-T segment abnormalities were seen on electrocardiogram in 61 percent whereas defects were present in 79 percent of those undergoing thallium-201 imaging ($p < 0.01$). The relative specificity in 33 patients without coronary disease was 82 percent for exercise electrocardiography and 85 percent for thallium-201 imaging. Of 69 patients who either had S-T depression 1 mm or greater or who attained 85 percent of their predicted heart rate, S-T segment depression was seen on electrocardiogram in 74 percent and a perfusion defect was seen on thallium-201 imaging in 84 percent. However, of 23 patients who did not reach 85 percent of maximal predicted heart rate, thallium-201 imaging detected 8 of 15 patients with coronary heart disease not found by the stress electrocardiogram, whereas all 8 patients with normal coronary arteries had normal findings on thallium-201 studies. It thus appears that thallium testing is relatively advantageous in patients unable to perform maximal stress.

TABLE I

Comparative Sensitivity and Specificity of Electrocardiographic Variables and Thallium Imaging for Coronary Heart Disease

	Patients (n)		Sensitivity (%)					Specificity (%)	
Investigator	Total	With CHD	Q	S-T	Q + S-T	Thallium Defect	Combined 201-T1 and ECG (%)	ECG-S-T	TI
Bailey et al.[14]	63	63	43	38	65	75	89	—	—
Ritchie et al.[15]	101	76	28	45	65	76	91	84	92

Ritchie et al.[18]	190	148	36	47	73	76	91	86	88
McCarthy et al.[19] †	128	95	43	64	79	85	93	85‡	79
Bodenheimer et al.[20]	95	73	26	56	71	81	84	86	88

* Data in table are based only on patients with isoelectric S-T segments at rest.
† See text for more detailed analysis of these data by subsets.
‡ Twenty normal patients with interpretable test.
CHD = coronary heart disease; ECG = electrocardiogram; TI = thallium.

Effect of baseline S-T and T wave abnormalities: A well known limitation of the exercise electrocardiogram is the difficulty in evaluating induced S-T segment abnormalities in patients taking digitalis preparations or exhibiting baseline electrocardiographic abnormalities such as left bundle branch block, left ventricular hypertrophy or marked ST-T deviation.[14–16,18,19] Ritchie et al.[18] analyzed 16 such patients, of whom 13 with angiographic evidence of coronary heart disease demonstrated perfusion defects on thallium-201 imaging. Similar findings have also been reported in such patients by others.[14–16,19] Therefore, thallium-201 imaging is also of particular value in this subgroup.

Detection of multivessel disease: The relatively poor prognosis of patients with multivessel coronary heart disease has highlighted the importance of using appropriate noninvasive studies to identify this subgroup.[33,34] Of concern in detecting patients with multivessel disease is the possibility of a relatively homogeneous or global ischemia. Since thallium-201 imaging provides data on relative and not absolute myocardial perfusion, the result might be the illusion of a normal image. In view of the high rate of detection of patients with three vessel disease, this diagnostic pitfall appears to have been avoided. However, in our experience, thallium-201 imaging alone has a sensitivity in patients with two or three vessel disease similar to that of electrocardiographic variables (S-T depression or abnormal Q waves, or both) when analyzed separately (Table II). Similarly, Bailey et al.[14] found that in patients with two vessel disease, electrocardiographic abnormalities allowed detection in 70 percent compared with 65 percent of those undergoing thallium-201 imaging. In patients with involvement of three vessels, the disease was detected by electrocardiogram in 93 percent and by thallium-201 imaging in 93 percent. However, as seen in Table II, the combination of findings on thallium-201 imaging with electrocardiographic variables allowed for the detection of additional patients at all levels of severity of coronary disease not detected by electrocardiographic criteria (Q waves or S-T abnormalities, or both) alone. Thus, in our series, thallium-201 imaging detected five of six patients with three vessel disease and submaximal stress. The additional diagnostic value of combining thallium-201 imaging with the rest and stress electrocardiogram has also been reported by others.[16,19,35]

TABLE II

Relation of Noninvasive Tests to Extent of Coronary Heart Disease

Findings	Obstructed Coronary Arteries (n)					
	1 (19 pt)		2 (29 pt)		3 (36 pt)	
	n	%	n	%	n	%
Pathologic Q waves	6	32	8	28	9	25
S-T depression ≥ 1 mm	5	26	20	69	26	72
Q and/or S-T	9	47	23	79	30	83
Thallium defect	13	68	22	76	31	86
Q + S-T + thallium defect	15	79	26	90	34	94

pt = patients.

The fact that absolute regional thallium-201 flow distribution cannot be determined does limit determination of the *number* of obstructed vessels in any single patient. We examined the consequences of this in 25 patients with multivessel disease, each of whom had at least one vessel with total obstruction. In eight patients with two vessel disease, eight of nine vessels with 100 percent obstructive lesions had associated regional defects. However, in only four of seven zones supplied by coronary vessels with more than a 75 percent lesion were associated regional defects found. Similarly, in 17 patients with three vessel disease, 15 of 18 vessels with 100 percent obstructive lesions had regional perfusion defects. Of the remaining 33 zones supplied by vessels with 75 to 99 percent obstruction, only 14 had associated regional defects. Other investigators[16,34,36] have reported similar difficulties in detecting the number of involved vessels.

False positive stress tests: Thallium imaging has been evaluated as a means of distinguishing patients with a true positive electrocardiographic stress test from those with a false positive test. Thus, in the multicenter trial,[18] specificity of thallium-201 imaging was 93 percent with only three definite false positive studies. Several other studies have similarly reported a high specificity for thallium-201 imaging in the diagnosis of coronary heart disease (Table I). In addition, the results of several small series suggest that thallium-201 imaging is also of value in the *asymptomatic* patient with a suspected false positive test.[37,38] It is apparent, however, as recently reported in 27 consecutive patients with chest pain without obstructive coronary disease,[39] that although the specificity of thallium-201 imaging was 85 percent compared to 63 percent for electrocardiographic stress tests, overlap does occur so that all false positive S-T responses will not be revealed.

Recent data have also demonstrated that occasionally a patient with S-T depression on stress electrocardiography and a normal thallium-201 image may, in fact, have coronary heart disease. Thus, of 84 patients with coronary disease studied in our laboratory, 6 patients with coronary disease (including 5 with multivessel disease) had an abnormal S-T segment response to stress despite a normal thallium-201 perfusion scan. Other investigators have found similar results. Bailey et al.[14] described three patients with abnormal S-T segments and a normal thallium-201 image. Leppo et al.[40] studied 30 patients with three vessel disease, of whom 3 had a positive stress electrocardiogram and a negative thallium-201 perfusion. Similarly, McCarthy et al.[19] found seven patients with a positive stress electrocardiogram and a negative thallium-201 study.

Clinical indications for exercise thallium-201 imaging to diagnose coronary heart disease: It is clear from the cumulative experience cited that thallium-201 is not a definitive diagnostic test in patients with suspected coronary artery disease. The clinical usefulness, limitations and indications for thallium-201 studies, therefore, should be determined by the clinical context in which it is being considered, including age and sex of the patient and description of the chest pain. Of possible concern, however, is the applicability of

current published data to evaluation of the role of thallium imaging in women because of the small numbers in these series. In men with *classic angina pectoris* the overwhelming majority of patients have coronary heart disease.[41,42] In such patients, the resting and exercise electrocardiogram provides some additional information[42,43] regarding the severity of the disease and prognosis. Exercise thallium-201 imaging for diagnostic purposes detects few additional patients and therefore may not be necessary if the stress electrocardiogram is unequivocally positive. In women with classic angina, approximately one half have coronary artery disease.[42] Exercise testing, as in men, adds some useful information. However, no specific information concerning thallium imaging is available in this subset and it is conceivable that this test might be of additional value. If the stress test is suboptimal and the evaluation of S-T segment abnormalities on electrocardiogram is difficult or is being made as a baseline prior to coronary arterial bypass graft (see later), thallium-201 imaging plays a more important role.

In patients with clearly noncoronary chest pain, the incidence of coronary heart disease is exceedingly low both in men and in women, although age is an important factor.[42,43] If an electrocardiographic stress test is positive in this situation, a thallium-201 study often provides useful clarifying information. If negative, it supports the impression that the chest pain is nonischemic in nature (although the finding is not definitive). In contrast, if positive, the test raises the strong likelihood that myocardial ischemia is indeed present. The same reasoning would apply to persons who are *asymptomatic* but who have a *positive stress electrocardiogram.*[37,38]

There is a middle group of patients with atypical chest pain whose clinical diagnosis is unclear. Coronary heart disease is present in about one-half of the men and approximately one-third of the women, depending on age.[42,43] Although resting and stress electrocardiograms again yield additional information to clarify the diagnosis, thallium-201 imaging may be helpful as well. A positive thallium-201 study strongly suggests the presence of ischemia. But although a negative thallium-201 image makes the diagnosis less likely, it by no means excludes it. In this regard it is of interest that Hamilton et al.,[44] using Bayes' theorem, concluded that electrocardiographic and thallium studies prove most useful in groups in which disease prevalence ranges from 0.2 to 0.7.

Thallium to Assess the Physiologic Significance of a Coronary Obstruction

In view of the experimental studies showing a quantitative relation between graded regional coronary flow reduction and contraction abnormalities,[45] the interrelation among the severity of coronary obstructive lesions, asynergy as defined by contrast ventriculography performed at rest during cardiac catheterization and defects seen on thallium-201 myocardial perfusion has been studied in our laboratory.[30] Of 56 left ventricular zones supplied by coronary arteries with obstructive lesions of 75 percent or more, 31 showed asynergy, 24 of which also showed defects on exercise thallium perfusion testing. In contrast, of the 25 normally contracting zones supplied by significantly obstructed coronary arteries, only 3 showed a perfusion defect whereas 22 had normal myocardial perfusion.

The association among the actual quantitative severity of the coronary lesion, the presence of asynergy on contrast ventriculography and a myocardial perfusion defect: Of 17 zones supplied by vessels with 75 to 89 percent coronary obstructive lesions, 7 had asynergy, 3 of which had a perfusion defect. In contrast, of 10 normally contracting zones, all had normal perfusion with thallium. Of 39 zones supplied by vessels with more than a 90 percent obstructive lesion, 24 had zonal asynergy, 21 of which had an associated perfusion abnormality. In contrast, only 3 of 15 without asynergy and a greater than 90 percent stenotic lesion had associated defects. Massie et al.[46] similarly reported a close relation between the presence or absence of asynergy and perfusion defects. In their study, the relation between contraction and perfusion was actually better than that seen relative to coronary obstruction.

Hamilton et al.,[22] using resting thallium-201 imaging, also found a strong relation between normal perfusion and either normal or borderline contraction. Conversely, abnormal thallium-201 perfusion correlated with severe contraction abnormalities or pathologic Q waves, or both. These data are consistent with experimental studies of Selwyn et al.,[8] suggesting that thallium-201 imaging is sensitive to decreases in perfusion sufficient to cause ischemic contraction abnormalities or actual infarction, or both (see Theoretical Considerations). Thus, a thallium-201 perfusion defect strongly suggests the presence of an associated physiologically significant coronary obstructive lesion. It should also be clear, however, that the absence of a thallium-201 perfusion defect (or for that matter, a contraction abnormality) does not permit the conclusion that a significant coronary lesion may not exist.

Thallium Imaging to Differentiate Viable from Nonviable Myocardium in Chronic Coronary Heart Disease

The redistribution of myocardial thallium-201 as a function of time has been used to differentiate myocardial ischemia from myocardial infarction (scar) in patients undergoing stress thallium-201 imaging. Thus, Pohost et al.[10] restudied patients 1 to 4 hours after they underwent an exercise thallium-201 study that had demonstrated a perfusion defect on images obtained immediately after exercise. When reimaged, the defect was either partially or completely eliminated in eight of ten patients. In contrast, the defect persisted in the patients who had had a myocardial infarction. On the basis of these findings, it was suggested that sequential imaging at the time of exercise provides a means of distinguishing the transient perfusion abnormalities of ischemia from myocardial infarction.[10]

Subsequent studies have examined the phenomenon of redistribution and its significance in patients with exercise defects. Ritchie et al.[47] and Verani et al.[48] found

that partial and complete redistribution of thallium-201 was common. However, pathologic Q waves were not clearly associated with persistent perfusion defects. Thus, Ritchie et al. found that 6 of 13 patients with complete redistribution had pathologic Q waves in the corresponding zone. Verani et al.[48] found that of 25 areas with associated pathologic Q waves on electrocardiogram, 8 (32 percent) showed total redistribution and an additional 32 percent partial redistribution.

Postexercise redistribution scans versus resting scans: Blood et al.[49] compared redistribution scans 4 or more hours after exercise with resting scans in 62 patients with coronary heart disease. The findings on redistribution scans were similar to those on resting scans in 73 percent. Of the remaining 17 patients, 16 (including 11 patients with associated Q waves and asynergy) had defects in the 4 hour redistribution scans but *not* in the resting study. In addition, of 28 patients with pathologic Q waves and associated asynergy, 15 (54 percent) had resting defects, whereas 26 had defects on redistribution.[49] Differing explanations are possible for these findings. Both necropsy studies and recent studies in our laboratory have demonstrated that overall a good relationship exists between surface electrocardiogram, Q waves and myocardial fibrosis.[50] However, in some cases, Q waves can be associated with histopathologically normal myocardium. Because Q waves do not always indicate scar, the normal resting scans can be reasonably explained. On the other hand, the presence of defects seen on redistribution scans and not at rest may simply reflect the need for minimal amount of myocardium that must be involved before a defect can be detected. Thus, at rest, the size or location of the scarred area may be such that it is not visualized.[12,13] However, if myocardium surrounding this zone is rendered ischemic during exercise, thereby enlarging the involved zone, the defect now comprising scar and ischemic but viable tissue may be visualized. In addition, the finding that such persistent areas generally involve the inferior area raises the possibility that technical factors (for example, relatively poor target to background ratios and interference from liver uptake) may have resulted in difficulty detecting resting abnormalities in the inferior zone.[49]

In a study in our laboratory, the relation between thallium-201 redistribution and the state of the underlying myocardium, as determined by contrast ventriculography both at rest and after nitroglycerin administration, was examined.[30] Twenty-seven myocardial segments demonstrated thallium-201 perfusion abnormalities immediately after exercise, of which 17 normalized and 2 lessened after redistribution (Fig. 2). Of these 19 zones, 3 had normal contraction, whereas 15 exhibited reversible asynergy and 1 showed irreversible asynergy. In contrast, all eight zones that had persistent thallium-201 perfusion defects after exercise

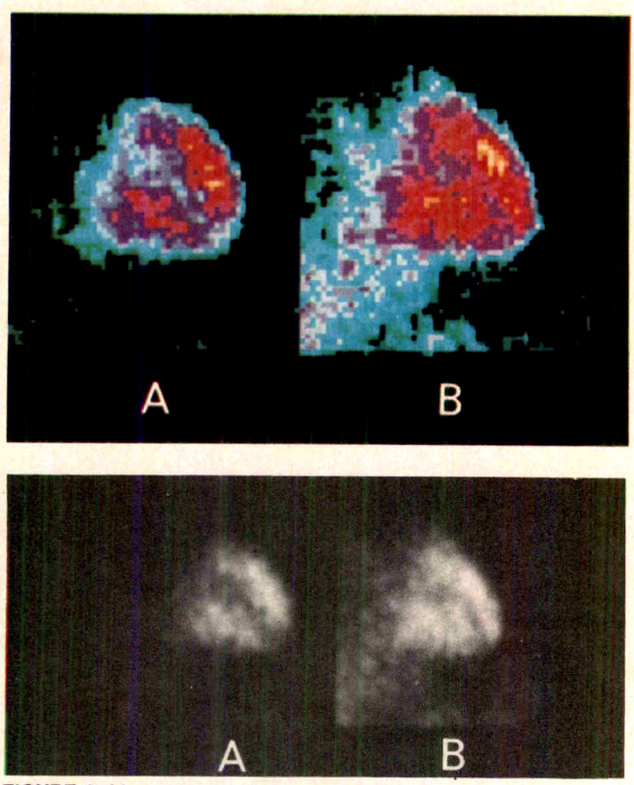

FIGURE 2. Myocardial perfusion scan in the anterior projection displayed as in Figure 1. An inferior defect that is seen immediately after exercise (A) normalizes in the redistribution image obtained after 2 hours (B). Black and white images (**bottom**) are displayed using identical background subtraction.

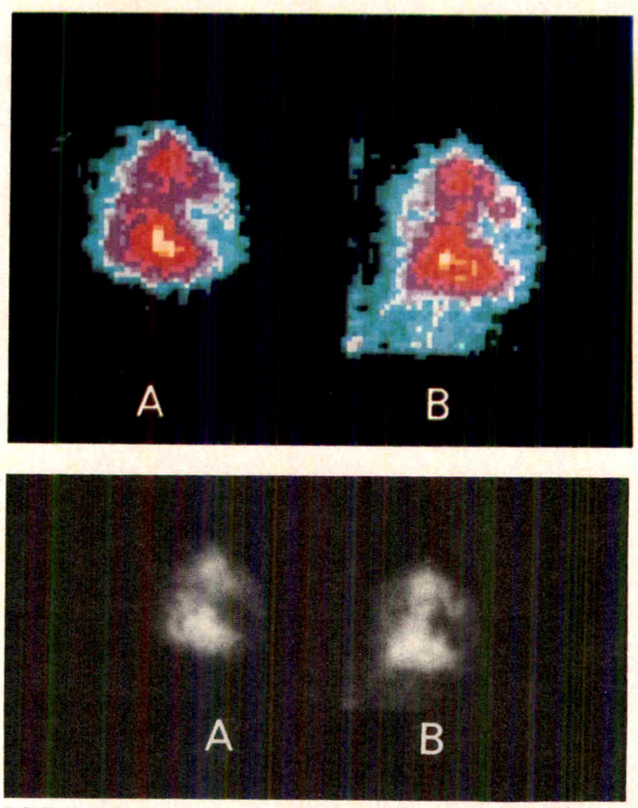

FIGURE 3. Myocardial perfusion scan in the anterior projection showing an anterior and apical defect immediately after exercise (**A**). Redistribution image (**B**) shows no significant change. Black and white images (**bottom**) are displayed using identical background subtraction.

had associated irreversible asynergy (Fig. 3). Of particular interest were the eight left ventricular zones with associated Q waves. Of these, four had irreversible asynergy and perfusion defects that remained unchanged after redistribution. However, all three zones with Q waves and exercise defects that normalized or lessened had reversible asynergy. Similar findings have also been reported by Massie et al.[46]

In summary, these data indicate that thallium-201 redistribution as a function of time after exercise is associated with viable myocardium which may be rendered ischemic during the stress, giving the resultant appearance of a perfusion defect. After a period of rest, during which normal myocardial metabolic function returns, thallium-201 can be adequately taken up from the blood pool with a resultant increase in counts. Partial thallium-201 redistribution is a more complex problem. Although the data suggest that the zones are usually composed of normal myocardium, the apparent redistribution seen may actually be consistent with a combination of fibrotic tissue not visualized at rest because of either the extent or location of the abnormality. When the surrounding myocardium is made ischemic during exercise, the extent of involved myocardium is increased sufficiently to permit detection.

Thallium Imaging in Noncoronary Heart Disease

Mitral valve prolapse: Thallium imaging has been recommended in several settings in which it is necessary to determine the presence of associated coronary heart disease. The most common of these is the patient with clinical evidence of mitral valve prolapse and chest pain consistent with coronary heart disease. Massie et al.[51] studied 25 patients with mitral valve prolapse, 6 with and 19 without coronary heart disease. Exercise S-T segment abnormalities were seen in 10 of 19 patients without coronary heart disease, whereas thallium-201 imaging was normal in all. Similar findings were reported in a smaller series of patients by Gaffney et al.[52] It should be pointed out, however, that occasionally a patient with mitral valve prolapse and normal coronary arteries has a perfusion defect. However, the significance of this finding in relation to the mitral valve prolapse is unclear at this time.

Aortic stenosis: Patients with *aortic stenosis* also are frequently suspected of having coexisting coronary disease. Bailey et al.[53] performed thallium-201 studies in 11 patients with aortic stenosis and angiographically insignificant coronary lesions and found focal defects in 5. So, whereas additional studies are clearly needed to confirm this observation, it appears that thallium-201 imaging is limited in this setting.

Cardiomyopathy: Thallium imaging has also been advocated to detect the presence of associated coronary heart disease in patients with *cardiomyopathy*. Thus, a frequent question is whether a congestive *cardiomyopathy* is, in fact, ischemic in origin. Bulkley et al.[54] evaluated a combined approach in such patients by using thallium-201 and radionuclide angiography. They found that although thallium-201 defects were present in patients with ischemic and nonischemic cardiomyopathy, the abnormalities were larger in patients with ischemic cardiomyopathy involving more than 40 percent of the left ventricular circumference in any one projection. Presumably the defects in patients without coronary disease were due to patchy nonuniform intramyocardial fibrosis. Rubin et al.,[55] in a series of 10 patients with idiopathic hypertrophic aortic stenosis and normal coronary arteries, found that 9 had normal findings on exercise thallium perfusion study.

Comparison of Exercise Thallium-201 Scanning and Exercise Radionuclide Angiography

Radionuclide angiography during exercise has also been advocated as a means of detecting coronary heart disease (see Nuclear Cardiology, Part I). To date, few studies are available that compare the noninvasive radionuclide and electrocardiographic stress tests available to detect coronary heart disease in patients with chest pain. In our laboratory,[56] 56 patients with angiographic evidence of coronary heart disease also underwent an exercise stress electrocardiogram with thallium-201 imaging and radionuclide angiography with isometric exercise. Exercise-induced S-T segment abnormalities were present in 58 percent. In contrast, exercise thallium-201 imaging and radionuclide-determined regional ejection fraction during isometric exercise each detected 82 percent ($p < 0.02$). The specificity of the two radionuclide techniques in 19 patients without obstructive coronary heart disease was similar. Thus, as a single test, each was superior to S-T segment testing; however, no clear advantage was apparent between exercise thallium-201 and radionuclide angiography. Similarly, preliminary data from other laboratories[57–59] comparing stress radionuclide angiographic assessment of global ejection fraction and wall motion with thallium-201 imaging did not show a clear superiority for either test (Table III). However, an analysis of the additional yield in patients after electrocardiographic stress testing has been performed suggests that radionuclide angiography performed at rest and during exercise may be the preferred technique.[56] For this reason, as well as the relative ease and shorter duration of the procedure and its smaller expense, we believe that exercise radionuclide angiography is currently preferable to exercise thallium-201 imaging. It must be remembered, however, that radionuclide angiography will detect an abnormal response in left ventricular function in noncoronary conditions (for example, valvular disease, hypertension or cardiomyopathy) and may be misleading in these circumstances.

TABLE III

Comparison of Exercise Thallium-201 Studies and Exercise Radionuclide Angiography to Detect Coronary Heart Disease

Investigator	Exercise Radionuclide Angiography	Exercise Thallium-201 Study

* Number of patients with a positive test/All patients with disease.

Use of Thallium Imaging in Assessing Coronary Arterial Bypass Surgery

In patients who have undergone coronary bypass surgery, the recurrence of symptoms raises the possibility of either a new obstructive lesion in the native coronary circulation or closure of a bypass graft. Ritchie et al.[60] studied 20 such patients (11 with preoperative resting and exercise thallium-201 and 9 with only preoperative resting thallium-201 imaging). After surgery, all patients had both resting and exercise thallium-201 studies as well as repeat coronary arteriography. Overall, a good relation existed between improved postoperative thallium-201 perfusion and the presence of patent grafts. In addition, postoperative perfusion defects were seen only in segments supplied by occluded grafts. However, in contrast, Rehn et al.[61] reported 24 patients similarly studied pre- and postoperatively. Utilizing improved perfusion either at rest or with exercise in the postoperative scans as the criterion for graft patency, they accurately predicted 25 of 39 (64 percent) of vascular segments as being supplied by patent grafts. However, when only *initially abnormal* segments were examined, 25 of 28 were accurately predicted as perfused by patent grafts. When worsening of or failure to lessen a preoperative exercise defect was used as an index of graft occlusion, only four of nine segments with occluded grafts were detected.[61]

It is clear that thallium-201 studies in this setting are limited by several factors. In patients with an obstructive coronary lesion who do not demonstrate a preoperative defect (31 percent in the series of Rehn et al.[61]), persistence of a normal postoperative scan is difficult to evaluate. If a new defect appears, this may not relate to the graft occlusion per se but to either a perioperative infarction[60] or progression of disease in a native vessel distal to the graft. Further studies are thus required to assess more fully the uses and limitations of thallium-201 imaging in patients undergoing coronary arterial bypass surgery.

Assessment of Acute Coronary Disease

Diagnosis of Acute Myocardial Infarction

Resting thallium-201 imaging has been extensively studied in patients with acute myocardial infarction.[18,29,62] Wackers et al.[62] evaluated 200 patients diagnosed as having an acute myocardial infarction based on electrocardiographic or enzyme criteria, or both, of whom 165 (83 percent) had perfusion defects at rest. Of particular interest was the relation between the time of onset of the infarction and its size as measured by peak enzymes. All 44 patients studied within 6 hours of the onset of pain had perfusion defects. In contrast, of those studied 24 to 48 hours after onset of pain, a defect was seen in only 21 of 36, whereas results were questionable in 13 and normal in 2. With regard to the size of the infarction, all 71 patients with a peak serum glutamic oxaloacetic transaminase more than 3.5 times the normal level had perfusion defects. In contrast, of the 25 patients with a lower transaminase level, only 19 patients had a defect.

In the multicenter trial reported by Ritchie et al.[18] 111 patients with an acute myocardial infarction but without a history of prior infarction had rest thallium-201 imaging an average of 5.4 days after onset of pain. Overall, 81 percent were positive for perfusion defects. However, in those studied within 7 days, 85 percent of scans were positive, whereas after 7 days, 70 percent were positive. In addition, the size of the infarct and its location were important determinants of the presence or absence of a defect on thallium-201 imaging. Thus, 39 of 41 patients with anterior Q waves had a defect, whereas only 27 of 37 patients with inferior Q waves had a defect. These studies indicate that the use of resting thallium-201 imaging is of somewhat limited value in the diagnosis of acute myocardial infarction because of its relative insensitivity. Although this is in part due to smaller infarcts and delay in imaging, from a purely diagnostic viewpoint thallium-201 scanning may be misleadingly negative.

An additional concern results from recent data[63] demonstrating that in patients with unstable angina given thallium-201 during a pain-free period perfusion defects can be demonstrated without enzymal evidence of infarction. Gewirtz et al.[64] found that even in some patients with stable angina and very severe coronary obstructive lesions perfusion defects can be demonstrated without symptoms or signs of acute ischemia or infarction. Because it is also clear that patients with an old infarct may have a defect seen on resting thallium-201 studies, it seems evident to conclude that as a purely diagnostic tool in patients with acute infarction, thallium-201 imaging is limited by its lack of both sensitivity as well as specificity.

Role of thallium-201 imaging in assessment of infarct size: Despite the limitations of thallium-201 imaging in the diagnosis of acute myocardial infarction indicated earlier, resting thallium-201 imaging has been one of several approaches that have been investigated to quantitate the size of an infarct. Experimental data[9,12] have shown a good correlation between the extent of myocardial necrosis and decreased thallium-201 perfusion. In addition, in a necropsy study by Wackers et al.[65] an excellent correlation was found between the size of an infarct as measured by thallium-201 imaging and that seen on pathologic study.

In this regard, Wackers et al.[62] performed serial studies in patients with acute myocardial infarction. Of 13 patients studied initially at 6 hours, 7 showed a decrease in the size of the defect at 24 hours. Of another group of nine patients restudied at 4 to 10 days after infarction, all showed a decrease in the defect. Similarly, of 15 patients first studied 24 hours after infarction, 7 showed a decrease and 8 no change in infarct size when restudied 4 to 10 days later. Although this is in contrast with results of an early report by Pohost et al.[10] suggesting that redistribution did not occur in acute myocardial infarction, a more recent preliminary report[66] by the same group indicates that some degree of redistribution occurred in 9 of 16 patients in whom serial images were obtained within 12 hours of the acute infarction. Whereas these data suggest that thallium-201 imaging may be able to delineate zones of myocar-

dium that, although ischemic, are potentially viable in the early phase of acute myocardial infarction, the rapid redistribution and variable time course severely limit its application to assess accurately the effect of interventions that might be utilized to modify infarct size.

Ischemia at Rest

Rest thallium-201 imaging has been reported in patients with acute ischemia at rest. Maseri et al.[67] administered thallium-201 to patients with variant angina during an episode of chest pain and found a perfusion defect in the corresponding zone. However, reimaging 2 hours as well as and 1 week later revealed normal perfusion, suggesting a reversible phenomenon.[67] Thus, thallium-201 imaging can be utilized to determine the presence of active ischemia. However, it should be clear that in view of the possibility of a perfusion defect, due either to scar or severe coronary obstructive disease (see earlier), a defect seen on resting thallium-201 imaging cannot be taken in itself as conclusive evidence of active ischemia.

Clinical Implications

Since the initial introduction of thallium-201 myocardial perfusion imaging, its uses and limitations have become better defined. At this time, its primary indication appears to be in the patient with suspected coronary heart disease who either is unable to exercise adequately or who has resting electrocardiographic abnormalities rendering interpretation of the S-T segment response difficult. In addition, in the patient with a suspected false positive exercise-induced S-T segment abnormality or with chest pain and mitral valve prolapse, a normal thallium-201 study is of value in confirming the clinical impression. In contrast, thallium imaging is of limited diagnostic value in the patient with the classic symptoms of angina and a diagnostic electrocardiogram (resting or exercise) and in the determination of the extent of coronary heart disease. In patients with suspected acute myocardial infarction, the high incidence of false negative results and the difficulties in interpretation of a perfusion defect in patients with acute ischemia limit its role in this setting.

Acknowledgment

We thank George Hermann, MD for his helpful comments and suggestions during preparation of this manuscript. We also thank Kathleen McNair and Jeanne Harrison for their secretarial assistance.

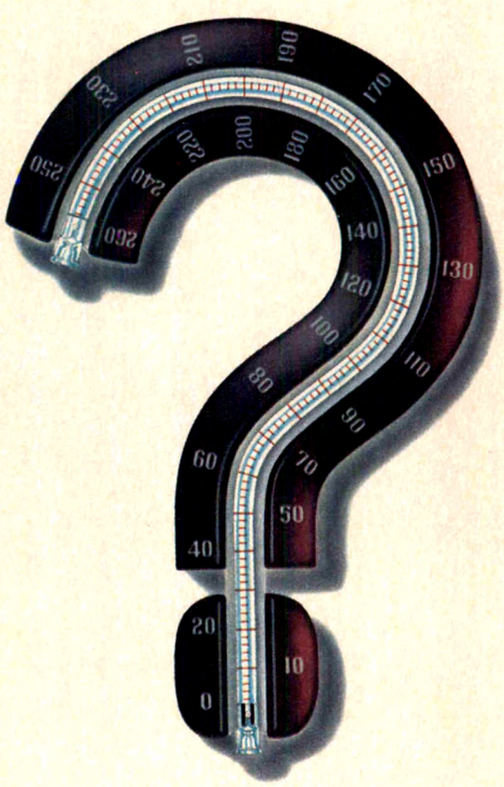
ANSWERS ABOUT ALDOMET®
(METHYLDOPA | MSD)

TO SOME IMPORTANT QUESTIONS ABOUT ANTIHYPERTENSIVE THERAPY.



MSD
MERCK SHARP & DOHME

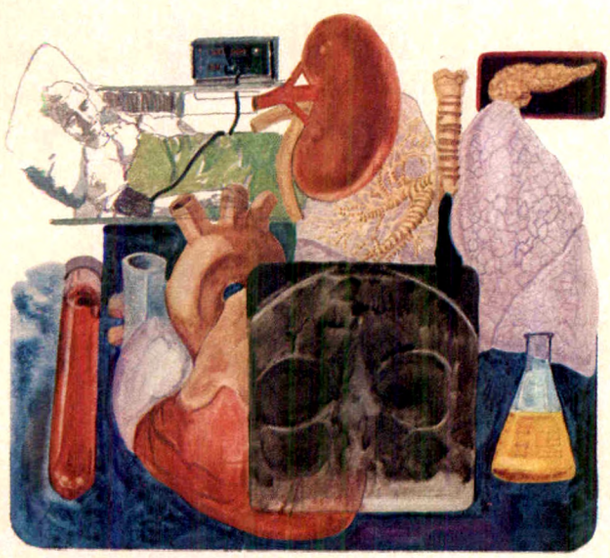
For a brief summary of prescribing information, please see last page of this advertisement.

IN ANTIHYPERTENSIVE THERAPY

...ANSWERS ABOUT

Can an antihypertensive be used in the vast majority of hypertensive patients, including certain patients requiring special considerations?

ALDOMET® CAN
(METHYLDOPA | MSD)



ALDOMET can be used in a wide range of hypertensives, including those with:

- ventricular hypertrophy
- hyperglycemia
- diabetes mellitus
- bronchial asthma
- allergic rhinitis
- hyperuricemia
- gouty arthritis
- sulfonamide hypersensitivity

ALDOMET (Methyldopa, MSD) is contraindicated in active hepatic disease, hypersensitivity to the drug, and if previous methyldopa therapy has been associated with liver disorders.

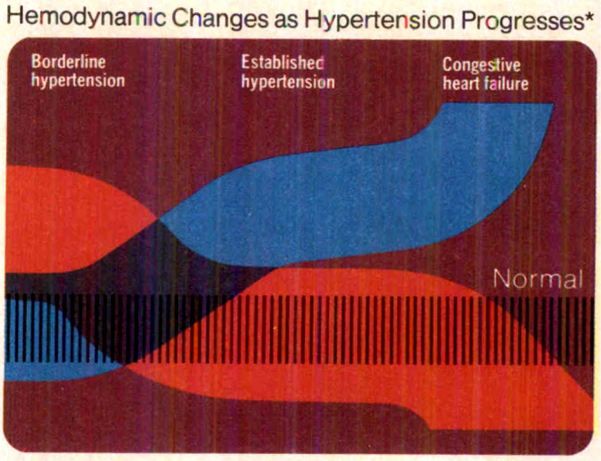
Copyright © 1979 by Merck & Co., Inc.

Does an antihypertensive lower blood pressure usually without lowering cardiac output?

ALDOMET DOES
(METHYLDOPA | MSD)

ALDOMET has no direct effect on cardiac function and lowers blood pressure usually without reducing cardiac output. Rather, it appears to reduce peripheral vascular resistance, the most commonly identified hemodynamic variable in hypertension (as hypertension progresses cardiac output tends to decrease and peripheral resistance tends to increase).

Hemodynamic Changes as Hypertension Progresses*



*adapted from Messerli and de Carvalho[1]

This may be particularly important in hypertensives with impaired cardiac function such as those with congestive heart failure*

*Edema may occur with ALDOMET. This is usually relieved by the use of a diuretic, but if edema progresses methyldopa should be discontinued.

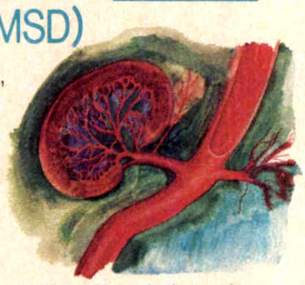
TABLETS: 500 mg, 250 mg, and 125 mg

ALDOMET®
METHYLDOPA | MSD)

The most prescribed nondiuretic antihypertensive in the U.S. today

Can an antihypertensive be effective usually without further reducing renal blood flow?

ALDOMET CAN
METHYLDOPA | MSD)



Glomerular filtration rate, filtration fraction, and renal blood flow are usually not reduced; therefore, ALDOMET is appropriate for many hypertensive patients with significantly impaired renal function. Since the drug is largely excreted by the kidney, patients with impaired renal function may respond to smaller doses.

Will an antihypertensive generally allow a normal cardiovascular response to exercise?

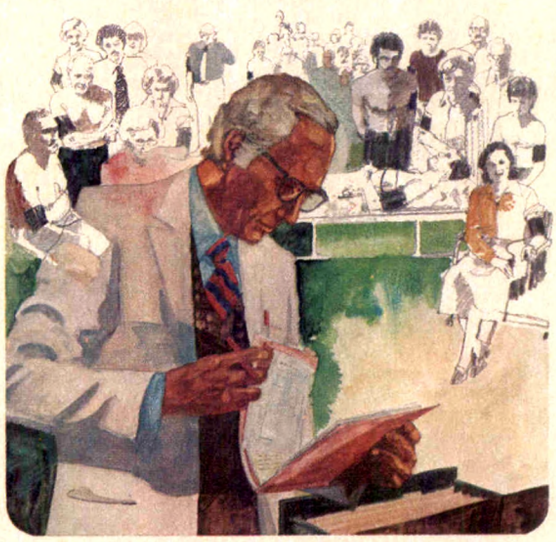
ALDOMET WILL
METHYLDOPA | MSD)

Cardiac output and blood pressure normally increase as the physical activities of the patient increase. ALDOMET does not significantly impair normal fluctuations of blood pressure during exercise.[2,3] This can be of importance to active hypertensive patients—such as athletic individuals or persons whose work requires substantial physical effort. With ALDOMET, exercise hypotension rarely occurs.

Sedation, usually transient, may occur during the initial period of therapy or whenever the dose is increased. Headache, asthenia, or weakness may be noted as early and transient symptoms.

Has an antihypertensive shown a proven record in long-term therapy?

ALDOMET HAS
(METHYLDOPA | MSD)



A recent study[4] followed a group of patients on ALDOMET for ten years or more. The results suggest that ALDOMET is a highly effective medication for the long-term management of hypertension.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed.

MSD MERCK SHARP & DOHME

For a brief summary of prescribing information, please see following page.

ALDOMET®
(METHYLDOPA | MSD)

The most prescribed nondiuretic antihypertensive in the U.S. today

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression.

Cardiovascular: Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.)

Gastrointestinal: Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis.

Hepatic: Abnormal liver function tests, jaundice, liver disorders.

Hematologic: Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor.

Allergic: Drug-related fever, lupus-like syndrome, myocarditis.

Other: Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets, containing 125 mg methyldopa each, in bottles of 100; Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000; Tablets, containing 500 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 500.

Is the patient drowning in crystalloids?

Deciding whether to treat with crystalloids or colloids a critical decision that is far from easy. Crystalloids an risk edema. Colloids can endanger the patient and eplete the pharmacy budget.

The IL186 WEIL ONCOMETER™ System provides reli- ble colloid osmotic pressure (COP) measurements to elp decide whether crystalloid or colloid fluid therapy called for. Monitoring COP also helps etermine extent of cardiopulmonary ailure, risk of pulmonary edema and emodynamic effects of dialysis.

Consider these IL Oncometer System eatures:

- The only system available with mercury manometer for accurate calibration
- Quality performance assured via assayed serum albumin
- Fast response time, stat results
- Long-life, easily replaceable membranes
- Flow-through, closed sample chamber
- Small sample size (300 μl)

Let the IL Oncometer System help keep your patient and your pharmacy budget out of troubled waters. For a demonstration or further information, call IL **toll-free: 800 225-4040** (800 342-8856 in MA) Or write for technical papers on COP and its clinical importance.

For specific ventricular arrhythmias* The evidence

Before prescribing Norpace (disopyramide phosphate), please consult current complete prescribing information, a summary of which follows: **Indications:** Norpace is indicated for suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in treating the above arrhythmias in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or in patients with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Severe hypotension has been observed primarily in patients with primary cardiomyopathy or inadequately compensated congestive heart failure. If hypotension develops Norpace should be discontinued promptly unless hypotension is due to the arrhythmia. Norpace should not be used in the presence of poorly compensated or uncompensated congestive heart failure unless it is exacerbated by or caused by an arrhythmia and proper treatment including optimal digitalization has been accomplished.** In patients with marginally compensated heart failure or with a history of heart failure, Norpace may worsen cardiac decompensation. In these patients, progressing congestive heart failure should generally be treated with cardiac glycosides and diuretics and the course of treatment closely followed. Norpace dosage should be reduced or discontinued if adequate control of congestive failure is not attained. Patients receiving concomitant therapy with more than one antiarrhythmic drug must be carefully monitored for serious negative inotropic effects or excessively prolonged conduction evidenced by widening of the QRS complex and/or prolongation of the Q-T interval. If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of the benefit versus the risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic properties, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. **Precautions:** If significant widening (greater than 25%) of the QRS complex occurs, Norpace should be discontinued. If Q-T prolongation greater than 25% occurs and if ectopy continues, monitor closely and consider discontinuing Norpace. Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace. Norpace should be administered cautiously to patients who are receiving or who have recently received other antiarrhythmic drugs. Excessive widening of the QRS complex and/or prolongation of the Q-T interval may occur in such instances. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace therapy. Use in Pregnancy and Lactation: Safe use in pregnancy has not been established. Norpace has been reported to stimulate contractions of the pregnant uterus. The use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. It is not known whether disopyramide is excreted in human milk. However, studies in rats have shown that the concentration of disopyramide and its metabolites is up to three times greater in milk than in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Labor and Delivery: The effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown. Pediatrics: The safety and effectiveness of Norpace in children have not been established. **Adverse Reactions:** Anticholinergic: dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention. Genitourinary:

*Indicated for premature ventricular contractions (PVCs)... unifocal, multifocal, or paired PVCs... episodes of ventricular tachycardia.

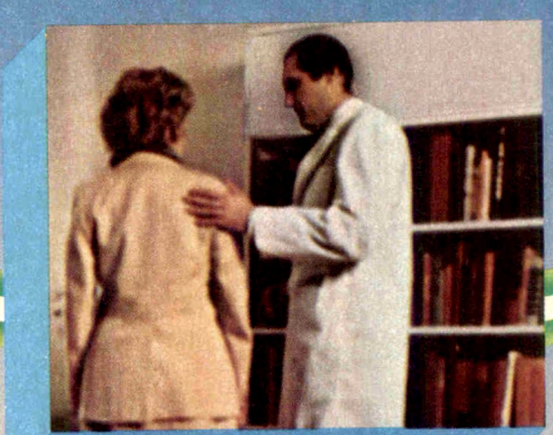
continues to mount

Norpace®

(disopyramide phosphate)

more compatible than quinidine in the digitalized patient

for hospitalized patients when oral medication is indicated



...as initial therapy in most outpatients

A high percentage of digitalized patients are also receiving a Type 1 antiarrhythmic. In the case of quinidine, concurrent administration of digoxin can result in an elevated serum digoxin level. Some studies have indicated that quinidine molecules appear to displace digoxin from binding sites in skeletal muscle and other tissues.[1-3] *Other researchers have observed that quinidine may reduce the renal clearance of digoxin, thereby prolonging serum digoxin levels.*[4] *In any case, an elevated serum digoxin level may lead to digitalis intoxication.*[2-4]

Norpace (disopyramide phosphate) does not appear to elevate serum digoxin levels when digoxin is combined with disopyramide in therapeutically effective doses.[4,5] *Thus, for your patient receiving combined digoxin and Type 1 antiarrhythmic therapy with Norpace, the risk of digitalis intoxication is reduced, and patient monitoring and digoxin dosage adjustment are facilitated. Norpace... the Type 1 antiarrhythmic attuned to the demands of both you and your patients. Consider these other benefits of Norpace:*

- **Demonstrated efficacy**
- **More favorable side effects profile than quinidine**
- **Lower dropout rate than with quinidine**
- **High level of compliance**

urinary frequency and urgency. Gastrointestinal: nausea, pain/bloating/gas, anorexia, diarrhea, vomiting. General: nervousness, dizziness, general fatigue/muscle weakness, headache, malaise. Cardiovascular: hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain. Dermatologic: generalized rash/dermatoses. The following have occurred, but a causal relationship is uncertain: impotence, depression, insomnia, dysuria, and hypoglycemia (usually in patients with impaired liver function). Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported. **Dosage and Administration:** Dosage must be individualized for each patient on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients weighing less than 110 pounds (50 kg) the recommended dosage is 100 mg every six hours. If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients weighing less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg every six hours, with subsequent dosage adjustments made gradually under close monitoring. **See current complete prescribing information for dosage recommendations. How Supplied:** Capsules containing 100 mg or 150 mg of disopyramide base. Available in bottles of 100, 500, and 1,000 capsules, and cartons of 100 unit-dose individually blister-sealed capsules.

CPI'S® NEW POROUS TIP LEAD: THE PROBLEM SOLVER

PROBLEM: Endocardial Lead Dislodgement, Causing Threshold Rise or Loss of Capture.

SOLUTION: CPI's New Porous Tip Lead

CPI addressed the problem of lead dislodgement and designed the problem solver: a unique porous electrode. The tip consists of a platinum-iridium screen covering a mesh ball of the same alloy. Optimally-sized fibers give 85-90% porosity so tissue ingrowth knits the tip to the endocardium. Within 24 hours post-implant, the electrode begins its embedment. Clinical studies have demonstrated markedly reduced dislodgement with the porous tip lead. In animal trials, the dislodgement rate was significantly lower than the solid tip control group.[1]

Histologic studies show tissue ingrowth in the acute phase, resulting in a secure electrode-tissue bond chronically, with a noticeably thinner and more structured fibrotic capsule that increases sensing capability.

PROBLEM: An Electrode Tip Must Be Small to Pace Efficiently, but Large Enough to Sense Effectively.

SOLUTION: CPI's New Porous Tip Lead

For pacing the 7.5mm^2 tip offers reduced current drain, increasing the longevity of constant voltage pulse generators.

For sensing the tip's porosity allows maximum use of the effective sensing area—more than 50mm^2—on exterior and interior surfaces. Presence of tissue and fluid within the tip reduces polarization losses. The electrode transmits a larger R-wave, so it offers a sensing advantage.

PROBLEM: Fibrotic Capsule at Lead Tip Can Reduce Chronic Sensing Ability.

SOLUTION: CPI's New Porous Tip Lead

The platinum-iridium mesh fibers are 25μm in diameter, approximating cardiac cell size and thus minimizing tissue reaction.[2] The electrode becomes an integral part of the endocardium. Similar success has been experienced with Dacron fibers of the same size used in artificial heart valves.

Biocompatible size and quick stabilization mean the electrode causes very little endocardial irritation. Our histologic studies reveal that the fibrotic capsule surrounding the porous tip is significantly thinner than the capsule around a solid tip. The capsule is typically more structured, further indication of this electrode's biocompatibility.

Slimming the fibrotic capsule has significant results—the cardiac signal amplitude and slew rate remain high, so the lead senses reliably in the chronic phase.

Low Dislodgement Rate.. Efficient Sensing and Pacing...the Problem Solver from CPI.

Shown 24 hours post-implant, a cross-sectional 100X magnification of the porous tip-canine tissue interface. A fibrinoid collagen capsule has penetrated the outer lattice. Optimally spaced platinum-iridium fibers have allowed electrode ingrowth to begin.

Shown five months post-implant, a cross sectional 100X magnification of the porous tip-canine tissue interface. Dense connective tissue has penetrated the intraelectrode spaces. The fibrotic capsule measures about 300 microns in thickness.

©1979 Cardiac Pacemakers, Inc.

CPI POROUS TIP ENDOCARDIAL LEADS Models 4115, 4116 and 4117 are available in 52, 59 and 85 cm lengths, respectively. All are unipolar, with double-wound conductors of corrosion resistant MP35N nickel alloy. Silicone rubber sheaths the conductors and ends in a flange behind the porous platinum-iridium tip. The outer screen of fibers 40μm in diameter secures the electrode mechanically and assures less traumatic bonding with endocardial tissue. Fibers of the interior mesh are 25μm in diameter to reduce tissue reaction and promote sensing. The unique porous tip is constructed by an advanced bonding technique, which fuses the wire bonds and maintains the integrity of the platinum-iridium electrode without compromising the random configuration.

Alpha Stimulation

Central Control of Blood Pressure*

"The Family of Man" by Roberto Moretti,
a statuary in crystal symbolizing the broad range of
hypertensive patients eligible for therapy with Catapres.

The Alpha Advantage:

It's for all kinds of hypertensives

- *Unlike beta blockers, Catapres® has no contraindications.*
- *Catapres can be useful even in these patients with:*

Congestive heart failure	Allergic rhinitis
Ventricular hypertrophy	Hepatic disease
Hyperglycemia	Hyperuricemia
Diabetes mellitus	Gouty arthritis
Bronchial asthma	Sulfonamide hypersensitivity

Like any antihypertensive, use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

work/play—normal hemodynamic responses to exercise maintained.

love—low incidence of impotence and/or loss of libido: 2.8% in 1,923 patients studied.[1]

cardiac output—tends to return to control values during long-term therapy.

blood flow—preserved in kidney.

No Single Advantage Determines Drug Choice.

Other factors must include:

The drug's effectiveness in a given patient, its side effects, warnings, precautions, tolerance, etc. A rational therapeutic choice depends on a careful assessment of all such factors.

*Central alpha-adrenergic stimulation decreases sympathetic outflow from the brain, as shown in animal studies.

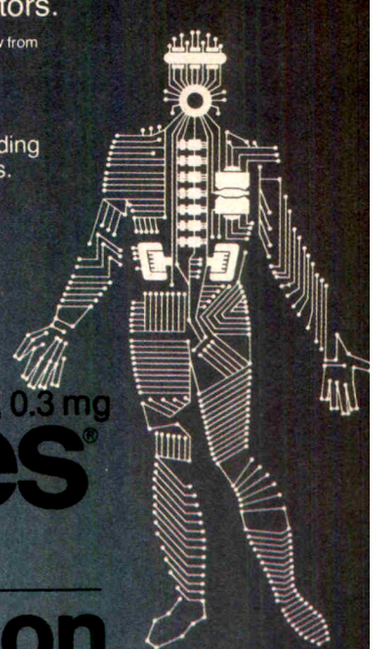
Please see last page for brief summary, including warnings, precautions, and adverse reactions.

Now available in new 0.3 mg tablets

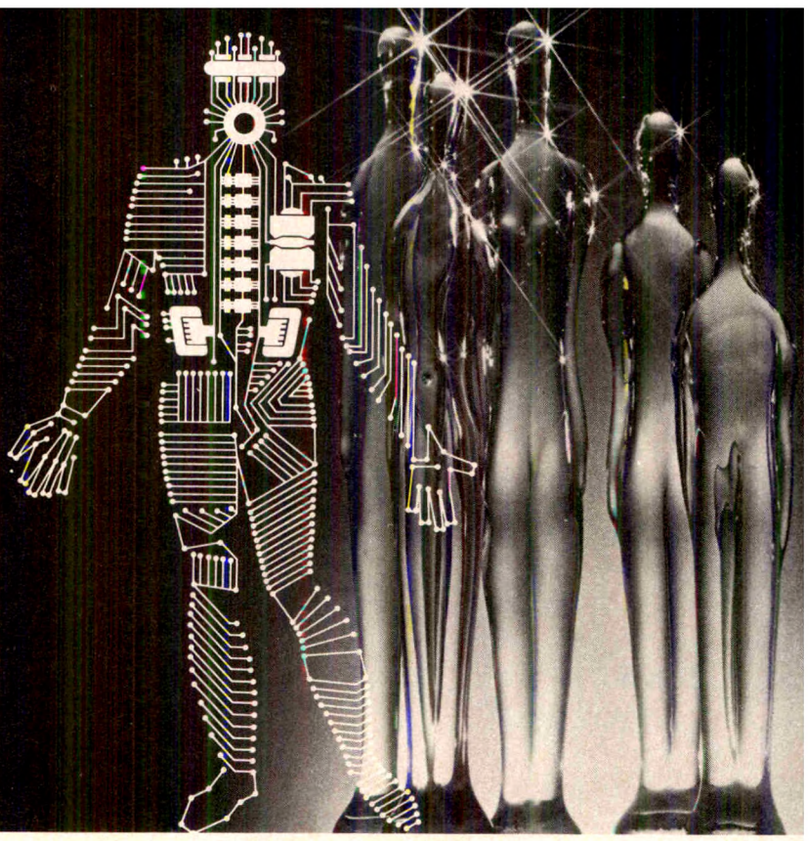


Tablets of 0.1, 0.2, 0.3 mg

Catapres®
(clonidine HCl)
Hypertension

The Alpha Advantage:

It's for all kinds of hypertensives



Tablets of 0.1, 0.2, 0.3 mg

Catapres®

(clonidine HCl)

Hypertension

- No contraindications.
- Effective in all degrees of hypertension. It is mild to moderate in potency.
- Low incidence of depression, impotence, orthostatic hypotension—no fatal hepatotoxicity.
- Preserves kidney blood flow.

Most common side effects are dry mouth, drowsiness, and sedation which generally tend to diminish with time.

The usual starting dose of Catapres is 0.1 mg at breakfast and 0.1 mg at bedtime. Some patients may benefit from a starting dose of 0.1 mg at bedtime.

Usual daily dose range—0.2—0.8 mg

Maximum daily dose—2.4 mg
Doses as high as this have rarely been employed.

For optimal results, the dose of Catapres must be adjusted according to the patient's individual blood pressure response.

Catapres®
(clonidine hydrochloride)
Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.
Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness/sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase: congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema. hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres, (clonidine hydrochloride) overdosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.

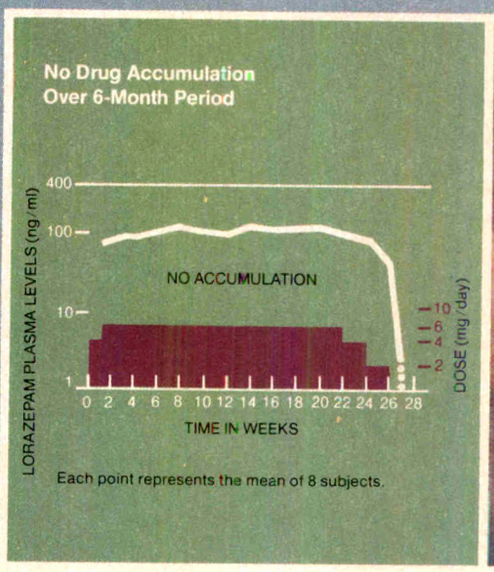
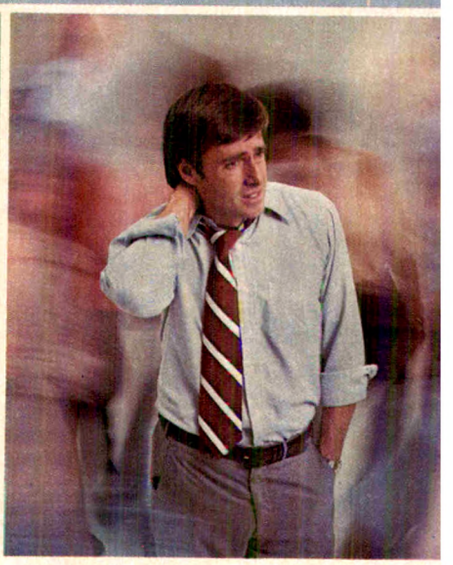
How do you choose a minor tranquilizer?





Wyeth Laboratories
Philadelphia, PA 19101
™

Pharmacokinetics

Ativan (lorazepam) is eliminated more rapidly than other benzodiazepines; generates no clinically active metabolites. The half-life of free lorazepam is about 12 hours; steady-state blood levels are attained in 2-3 days. (Comparable data for diazepam: 20-50 hours and at least 7-10 days.) Ativan shows no evidence of accumulation, even when given in high doses for as long as 6 months. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Anxiety neuroses

In many nationwide studies involving thousands of patients with anxiety neuroses, Ativan (lorazepam) consistently provided significant relief of anxiety, tension, agitation and irritability as measured by standard Hamilton, Global (physician rated) and 35-Item (patient self-rated) scales.

Copyright © 1979 Wyeth Laboratories Div. of AHPC, N.Y., N.Y. All rights reserved.

They're all about the same, aren't they? Until recently, that seemed to sum up the prevalent attitude about the benzodiazepines. After all, they all work similarly and all are effective anxiolytics. With seven of these compounds now available, however, differences have begun to emerge. Foremost among them: different metabolic pathways, which distinguish the relatively short-acting Ativan (lorazepam) from long-acting diazepam, clorazepate and chlordiazepoxide. At the same time, your choice can be made with confidence in the clinical record of Ativan, which confirms its value in anxiety neuroses and in significant anxiety associated with functional or organic disorders, as well as in older patients.

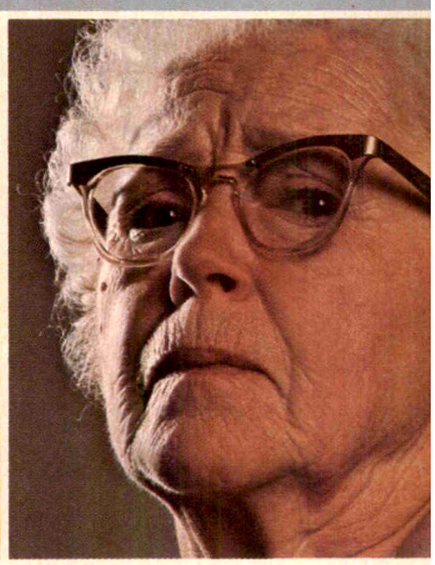
Consider the record of Ativan:

Anxiety in cardiovascular disorders

Ativan (lorazepam) has been specifically evaluated and found effective in seven common protocol, double-blind studies involving 423 patients (211 on Ativan) whose anxiety was related to organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in gastrointestinal disorders

So far, nine common protocol, double-blind studies of Ativan have focused on anxious patients with functional or organic gastrointestinal complaints (457 patients, 234 on Ativan). Ativan was clearly effective in reducing the anxiety of these patients. The gastrointestinal component has not, of course, been shown to be significantly benefited by such therapy.



Anxiety in the aging patient

Because its simple metabolism is not readily impaired with advancing age, and accumulation is not likely to present a problem, Ativan is a good choice for older patients. Those who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.

Ativan® (lorazepam) for Anxiety

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 15th Edition
Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Bonzales, R.Ph., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 15th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. They pass this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Only print material the manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one alphabetic sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main secton as follows:

- GENERAL INDEX of all brand generic names in a-z sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selectin of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

And, our Free Updating Service informs you of changes in specifications and introduces new drugs. You receive them free of charge until the publication of the next (16th) Edition.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

YORKE MEDICAL GROUP, 666 Fifth Avenue, N.Y., N.Y. 10019
Please send me a copy of the all-new 15th Edition of MODERN DRUG ENCYCLOPEDIA and enter my two year free subscription to the Periodic Updating Service. If this new edition is the best drug information reference for practitioners available, I will remit $38.95, plus shipping. Otherwise, I will return it within 30 days and owe nothing.

Calcification in Porcine Xenograft Valves in Children

MEREDITH M. SILVER, MB, BS, MSc, FRCP(C)*
JAMES POLLOCK, MD, FRCS(C)
MALCOLM D. SILVER, MD, PhD, FRCP(C)
WILLIAM G. WILLIAMS, MD FRCS(C)
GEORGE A. TRUSLER, MD, FRCS(C)

Toronto, Ontario, Canada

Calcification developed in the degenerating collagen of the cusps of three porcine xenograft heart valves implanted in children for less than 4 years. The morphologic features and effects of this calcification are presented. Calcification of porcine xenografts seems to occur more frequently and at an earlier stage after insertion in children than in adults. Host factors, possibly related to calcium homeostasis, may promote calcification; hence, these valves may not be appropriate for use in children.

Since 1977 there have been case reports[1–6] of 14 children with calcific stenosis in Hancock valves that had been implanted in the mitral (10 patients) or aortic (4 patients) valve position for 6 to 58 months. This report describes calcification occurring in Hancock valves placed in the aortic position in two teenage boys whose xenografts had been in place for 22 and 36 months, respectively. In a third boy calcific stenosis developed in a Hancock valve in the mitral position after 45 months; the patient died during an emergency operation to replace this valve. The morphologic features of the calcification are described in detail and the pathogenesis and complications are discussed.

Methods

The excised Hancock valves from Cases 1 and 2 were received intact and were photographed and subjected to X-ray examination. After fixation in 10 percent buffered formalin, sections passing from the free margin to the inner aspect of the metal ring were cut from the cusps and other sections were taken from the tissue lining the stents. Heavily calcified tissue was decalcified with 20 percent formic acid before being processed for paraffin embedding. Sections were stained with hematoxylin eosin, resorcin-fuschin, hematoxylin-phloxine-saffron, Masson's trichrome, Movat's pentachrome, Von Kossa, Gram and Gomori's methenamine silver.

Electron microscopy was performed on a small portion of xenograft cusp from Case 1. The specimen was fixed in 10 percent formalin, postfixed in osmium tetroxide and embedded in Epon-Araldyte. Ultrathin sections were cut, stained with uranyl acetate-lead citrate and examined with a Philips 201 electron microscope. It should be noted that glutaraldehyde tanning of the xenograft during its manufacture is equivalent to fixation for electron microscopy.

Case Reports

Case 1

This boy (HSC 1061146) had a heart murmur recorded at age 6 weeks. At 14 years he experienced progressive fatigue and shortness of breath on exercise. Investigation demonstrated a small ventricular septal defect with an aortic cusp prolapsing into it. The septal defect was closed and valvuloplasty performed. Because the boy had persistent aortic insufficiency postoperatively, 2 weeks later the aortic valve was replaced with a 23 mm Hancock porcine xenograft. The patient's own aortic valve had three separate cusps, and histologic sections revealed areas of fibroelastic sclerosis and focal myxomatous change; no calcification was present.

From the Departments of Pathology and Surgery, Division of Cardiovascular Surgery, The Hospital for Sick Children and the Departments of Pathology and Surgery, University of Toronto, Toronto, Ontario, Canada. Manuscript received August 9, 1979; revised manuscript received October 23, 1979, accepted October 24, 1979.

* Present address: Department of Pathology, St. Joseph's Hospital, London, Ontario, Canada.

Address for reprints: Department of Pathology, The Hospital for Sick Children, 555 University Avenue, Toronto, Ontario, Canada, M5G 1X8.

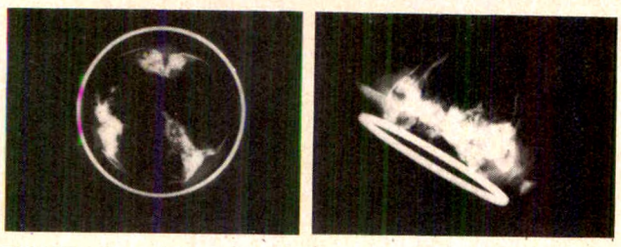

FIGURE 1. Case 1. X-ray films showing two views of excised Hancock xenograft valve. Nodular calcification is present in the cusps, most marked near the commissures. The laminar calcification in the pig aorta lining the stents can be seen in both views. (Actual size.)

The patient did well for 18 months and during this time he sustained three limb bone fractures in three separate skiing and soccer accidents. At age 15 1/2 years breathlessness, hemoptysis, cough and signs of congestive heart failure developed. A loud systolic ejection murmur was audible over the aortic area and the chest roentgenogram revealed pulmonary edema. Electrocardiograms demonstrated marked left ventricular hypertrophy with strain and an echocardiogram disclosed aortic stenosis. The stenotic heavily calcified Hancock valve was replaced 22 months after its implantation with a 25 mm Carpentier-Edwards porcine xenograft. The patient did well postoperatively.

FIGURE 2. Case 1. A valve cusp showing dark large and smaller calcium deposits within the collagen of the cusp fibrosa. The ventricular surface is to the left. (Masson's trichrome stain ×140.)

Valve description: The cloth-covered stents of the excised Hancock valve were covered with shiny smooth grey-white host tissue. The three cusps showed marked nodular calcification, particularly near the commissures (Fig. 1). The yellowish nodules in the cusps were covered by a filmy but smooth and shiny membrane on the ventricular surface, but they often formed rough granular excrescences on the sinus surface of the cusps. One cusp was stiff and fixed in the fully open position; the other two were pliable but only partially mobile. The maximal valve orifice diameter was 0.6 cm.

Microscopically, pig aorta was attached to the stents and pig myocardium was present in the valve ring. The aorta on the stents was sheathed by a thin layer of host collagen. The inner aspect of the ring was covered by a thick layer of densely collagenized host tissue that extended to the base of the cusps. Nuclei were present in normal numbers in the cusp fibrous tissue but stained paler than usual. The collagen lamellae of the cusp fibrosa were often focally disrupted, and focal calcification was obvious at some of these sites (Fig. 2). The calcification appeared to start in the fibrosa and to penetrate through the surface of the cusp, usually the sinus surface or the free edge. The large exophytic masses of calcium had thin strands of dense fibrous tissue from the cusp fibrosa admixed with them. Sheet-like calcification was present in pig aorta lining the stents (Fig. 1). A thin layer of fibrin covered the distal surface of the cusps close to their bases.

Electron microscopy showed collagen fibrils disintegrating into granular debris. Focal calcium deposits appeared to cover degenerating collagen fibers (Fig. 3). Similar calcium deposits were present in fibrillary cytoplasmic debris within degenerating cells and some deposits were continuous between the extracellular and intracellular zones.

Case 2

This boy (HSC 1025668) first presented at age 13 years after sudden shortness of breath, palpitations and tachycardia had developed while he was playing basketball. He was found to have aortic regurgitation and the valve was replaced with a 27 mm Hancock porcine xenograft. The native valve was bicuspid and sclerotic and had focal calcification at the free edge of one cusp.

The patient remained well for 33 months and was then readmitted with gross hematuria and a blood hemoglobin level of 8.9 g/100 ml. Examination, including cardiac catheterization, disclosed gross aortic regurgitation and stenosis. The congestive failure increased and the xenograft was replaced 3 years after its implantation with a 25 mm modified orifice Hancock porcine valve. Blood cultures taken at operation grew Hemophilus aphrophilus, and a portion of the excised valve grew the same organism. The patient was treated with the appropriate antibiotic drugs, and no further blood cultures were positive. Since then he has remained well.

Valve description: On gross examination all three cusps of the excised Hancock valve were frayed and ruptured. X-ray films revealed extensive calcification in the cusp tissue and in the pig aorta that lined the stents (Fig. 4).

Histologically, the valve cusps in some areas were thinned and frayed and also showed focal areas of collagen disintegration in the fibrosa with many such foci calcified. A few tiny foci of calcification were present in host tissue covering the tips of the stents but large masses of calcium were found at the base of the cusp remnants. These were mainly located in the dense collagen tissue of the graft but some masses broke through the surfaces of the cusps, disrupting host tissue that covered the base of the cusps. No fibrin was associated with the calcium masses. Sheet-like calcification also affected the

pig aorta lining the stents and was seen focally in pig myocardium incorporated in the xenograft ring. There was no evidence of either thrombosis or an active or healed endocarditis on the surface of the cusps. Special stains for microorganisms were negative.

Case 3

This boy (HSC 957726) had a primum type atrial septal defect repaired at age 10 years. There had been moderately severe mitral regurgitation, and at operation he was found to have a double orifice mitral valve. The valve was replaced with a 27 mm Hancock valve. Forty-five months later the boy died in the United Kingdom during an emergency prosthetic valve replacement necessitated by severe congestive heart failure. The excised valve was grossly calcified and its lumen obstructed.

Discussion

Incidence of porcine xenograft calcification: Some clinical reports[7–12] dealing with large series of patients treated with porcine xenograft heart valves and followed up for up to 7 years have indicated a small incidence of calcification in the grafts; other reports[13–16] do not mention calcification as a complication of this type of prosthesis. The patients in these reported series were probably adults, but most of the studies provide no information about the patients' age or sex or the site or duration of implantation of the xenograft. Also, the histologic localization of calcification is usually not stated. Pathologic studies of excised porcine xenografts have infrequently shown calcification. For example, Spray and Roberts[17] found calcification in only 2 of 18 Hancock valves excised 2 to 75 months after implantation. Ferrans et al.[18] demonstrated calcification (by X-ray examination) in only 1 of 12 Hancock valves implanted in patients for up to 76 months.

In contrast, there have been several reports[1–6] of calcification and calcific stenosis of xenograft heart valves in children; the data from these reports are shown in Table I for comparison with the findings in our three cases. Again, these reported studies pay little attention to the morphologic features of the calcification and they do not always indicate whether the calcium was present in host or graft tissue or in organized thrombi.

The 3 children in this report are from a series of 93 children with successful porcine valve implantation performed at our institution. Fifty-seven of these valves were incorporated in a conduit, and calcification has not yet been detected in any of these. Of the remaining 36 xenografts, 19 are in the aortic position, 9 in the mitral, 5 in the pulmonary and 3 in the tricuspid position. The follow-up time ranges from 4 months to 5 1/2 years. The incidence of calcification is less in our series than in those of others[4,6] cited in Table I; however, most of the xenografts in our series have been in place for shorter periods than the three that have failed.

Site and distribution of valve calcification: We found the calcification maximal in graft tissue and close to the commissures in our first two cases (Fig. 1 and 4). Such a distribution was not mentioned in other reports except that of Geha et al.[6] and would probably not be noted unless the pathologic specimen was subjected to X-ray examination. We observed in a 3 year old boy a similar distribution of calcium in an Ionescu-Shiley valve removed after 14 months in the mitral position because of stenosis due to organizing thrombi. We think this deposition may be at the sites of maximal stress as determined by in vitro testing of tissue valves.[19]

The more diffuse calcification found in the pig aorta lining the stents (Fig. 1 and 4) is in keeping with the known tendency of calcium to be deposited on elastic

FIGURE 3. Case 1. Electron micrograph of very electron-dense calcium deposits in the cusp fibrosa. The calcium coats degenerating collagen fibers, which are better preserved in the **upper left,** where their periodic banding is visible. Elsewhere collagen fibers are disintegrating and appear as granular debris. (Uranyl acetate and lead citrate ×47,500, reduced by 5 percent.)

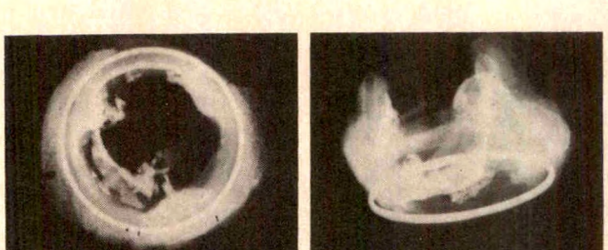

FIGURE 4. Case 2. X-ray films showing two views of excised Hancock xenograft valve. Cusp calcification is maximal near the commissures. Laminar calcification in the pig aorta lining the stents is particularly noticeable in the side view. (Actual size.)

TABLE I

Calcification in Pig Xenografts in Children: Comparison of Clinical Features of Reported Cases and Present Three Cases

Case Reference	Sex/Age (yr) At 2nd Operation or Death	Position of Prosthesis/Total Children in Series	Duration of Implantation (mo)	Clinical Course
Levitsky[1]	Male/9	Mitral	19	Severe calcific stenosis requiring valve replacement
Brown et al.[2]	Child/7	Mitral	36	Prosthetic stenosis, then sudden disruption of heavily calcified valve requiring its replacement
Rose et al.[3]	Male/14	Mitral	12	Patient died from severe calcific stenosis
Kutsche et al.[4]	3 children/2–15	Mitral/9	40	Calcific stenosis requiring valve replacement
			43	
			58	
Bachet et al.[5]	2 children/8–12	Mitral	6	Calcific stenosis requiring valve replacement
			16	
	Child/8–12	Aortic	26	Sudden aortic regurgitation with shock; valve replaced and found to have torn cusp as well as calcific stenosis
Geha et al.[6]	Female/11½	Aortic/11	26	Calcific stenosis requiring valve replacement; early postoperative death
	Female/14	Aortic/11	45	Calcific stenosis requiring valve replacement
	Male/17	Aortic/11	41	Calcific stenosis requiring valve replacement
	Male/7	Mitral/9	22	Calcific stenosis requiring valve replacement
	Female/11	Mitral/9	18	Calcific stenosis requiring valve replacement
Present series				
Case 1	Male/16	Aortic/19	22	Calcific stenosis requiring valve replacement
Case 2	Male/16	Aortic/19	36	Sudden onset of severe prosthetic regurgitation and hematuria requiring valve replacement; Hemophilus aphrophilus bacteremia
Case 3	Male/13	Mitral/9	45	Severe calcific stenosis with congestive heart failure; died during emergency replacement

fibers.[20,21] The occurrence of the calcification in the pig aortic tissue in broad sheets suggests that the stents may have been less flexible than their designers intended.

Our observations indicated that the calcification was focal, present most prominently within degenerating collagen lamellae in xenograft tissue. In our cases there were no thrombotic or infected vegetations. This focal distribution is in keeping with a local tissue factor postulated in dystrophic calcification (see Eisenstein[20] and Howell[22] for reviews).

In adults with xenografts such focal dystrophic calcification is rare, even in the presence of tissue deterioration.[17,23] It is rarer, indeed, than one might expect considering that nonviable tissue is bathed in blood and subjected to systemic blood pressure levels. The tanning with glutaraldehyde of porcine heart valves or prostheses made of other heterologous tissue and currently in use is considered the reason for their relative stability when compared with fresh or formalin-treated tissue valves.[23] However, the collagen of such valves and indeed of all tissue valves used until now gradually deteriorates, degenerates and may calcify. Prior treatment with glutaraldehyde may delay this process but does not stop it.

Mechanisms for valve calcification in children: The basic process of soft tissue calcification is still poorly understood. We believe that dystrophic and metastatic calcification may involve a similar mechanism. They are separated arbitrarily according to whether the serum calcium is "normal" or not. The calcification that occurs in porcine xenografts is usually considered dystrophic, but calcification in some xenografts may be metastatic and yet focal in distribution. Focal calcification in xenografts has been reported in patients requiring long-term hemodialysis because of chronic renal failure.[10,11] Such patients are known to have extensive soft tissue calcification that is not related to the known variables of calcium homeostasis.[24]

The apparently increased frequency of calcification in xenografts implanted in children suggests that a host factor in children may override the apparent protection against calcification conferred by glutaraldehyde pretreatment of tissue in adults. Possibly this host factor is related to calcium homeostasis. Children have a positive calcium balance[25] and have a more labile calcium homeostasis than do adults.[20] Our first patient was an exceptionally active boy who had broken bones during athletic activities in the 22 months his xenograft was in place. Our second patient had nodular calcification in the free edge of his native congenitally bicuspid aortic valve.

Examination of Table I suggests that in children with xenograft valves calcific stenosis is more likely to occur than rupture of a degenerated cusp and that the stenosis may precede such rupture. The latter event would be more likely than the former to result in a condition requiring emergency surgery. The calcific excrescences eroding through the cusp surface could form a nidus for infection. This appears to have occurred in our Case 2 because Hemophilus aphrophilis was cultured from several blood samples just prior to operation as well as from a portion of ruptured cusp, although the patient

had had no evidence of endocarditis in the 2 1/2 months during which severe aortic regurgitation was apparent prior to this operation.

Indications for use of porcine xenograft valve in children: In adults xenograft failure occurs because cusp perforation develops as a result of localized areas of collagen degeneration.[23] Carpentier et al.[23] state that the ". . . nature of the occasional valve failure is progressive and thereby permits elective reoperation under optimal conditions." Thus, in children, the risk of possible development of calcific stenosis in a xenograft valve might be a preferable to the risk of possible sudden disruption. However, because calcification apparently occurs so prematurely in children with the xenograft valve,[1–6] these prostheses may not be appropriate in this age group. Possibly, in children, the presence of calcification in a failed xenograft or in an excised native valve is an indication for valve replacement with a nontissue prosthesis. At our institution we continue to use porcine xenograft valves because the avoidance of anticoagulation in active children is very desirable. In addition, the young child requiring mitral valve replacement will need frequent reoperation (perhaps within 5 years) to replace the prosthesis in a larger valve in order to accommodate the child's growth. The continuing need for development of a prosthetic valve with improved hemodynamics that can be used without anticoagulation is particularly obvious in children.

Severe Calcification of Glutaraldehyde-Preserved Porcine Xenografts in Children

FRANCIS T. THANDROYEN, MRCP (UK)*
IAN N. WHITTON, FRCS (Edin)
DUNCAN PIRIE, FFPath (SA)
MICHAEL A. ROGERS, FRCS (Eng)
ABDUL S. MITHA, MRCP (Lond)

Durban, South Africa

Despite the widespread use of glutaraldehyde-preserved porcine xenografts, severe short-term calcification of these valves has been infrequently reported. This report describes four cases of glutaraldehyde-preserved porcine xenografts in the mitral valve position in which severe calcification occurred within 17 to 25 months of implantation. All four patients were children, aged 13 to 15 years.

The clinical presentation in all four cases occurred at a late stage when there was severe xenograft obstruction, with acute symptoms of cardiac decompensation in the presence of pulmonary hypertension and right heart failure. There was rapid cardiac deterioration resulting in a low output state and episodic pulmonary edema necessitating urgent mitral valve replacement. In only one case was there clear auscultatory evidence of severe mitral stenosis. Calcification of these xenografts occurred in the presence of normal serum calcium levels and was not related to infective endocarditis.

Histologic examination of the calcified xenografts strongly suggested dystrophic calcification resulting from primary collagen degeneration. The exact cause is unclear, but it appears that glutaraldehyde-preserved porcine xenografts may produce severe short-term calcification with acute hemodynamic deterioration necessitating urgent valve replacement and that this accelerated calcification may be a complication in young persons.

The glutaraldehyde-preserved stented porcine xenograft has been widely used as a substitute cardiac valve, and in many centers it has become the prosthesis of choice; yet very little is known regarding the structural and pathologic changes of this valve after implantation.[1–8] Valve-related complications of this type of valve prosthesis have been uncommon, and its major advantage over the nonbiologic prosthesis has been the low incidence rate of thromboembolism without anticoagulation.[1,9,10] Other complications described in common with other valve prostheses have been perivalve leaks, infective endocarditis, thromboses, calcification and overgrowth of fibrous tissue with interference of valve function.[3,4,9,11–13]

Severe stenosis of the glutaraldehyde-preserved porcine xenograft due to severe short-term calcification has been extremely rare; only two previous case reports[14,15] have described this problem with the xenograft in the mitral valve position. This rarity is remarkable when one considers the widespread use of the prosthesis over the last 7 years. This report describes four cases of severe calcification of glutaraldehyde-preserved porcine xenografts in the mitral valve position producing critical obstruction. All the patients were less than 15 years of age and underwent subsequent valve replacement. All are now well.

From the Cardiac Unit, Wentworth Hospital, University of Natal Medical School, Durban, South Africa. Manuscript received September 4, 1979, accepted September 26, 1979.

Case Reports

Case 1

A 15 year old Indian boy underwent mitral valve replacement with a 31 mm glutaraldehyde-preserved Carpentier-Edwards xenograft for mixed mitral valve disease. His postoperative course was uneventful and he was followed up after discharge for 7 months; during this time no murmurs were heard. He then defaulted for 14 months and presented again with a history of orthopnea and swelling of the legs of 1 week's duration. There was no history of intervening treatment, hospitalization or infective endocarditis.

On examination, there was no fever, pallor or clubbing. The pulse rate was 120/min, regular and of small volume. The blood pressure was 90/70 mm Hg and the jugular venous pressure was elevated at 5 cm. A grade 3/6 pansystolic murmur was present at the apex, but no diastolic murmur was audible. The pulmonary component of the second heart sound was markedly accentuated. Bilateral crepitations were present in the chest; the liver was tender and palpable 7.5 cm below the costal margin.

An electrocardiogram showed sinus rhythm at a rate of 120/min, a mean frontal QRS axis of +100° and evidence of right ventricular hypertrophy. The chest X-ray film demonstrated an enlarged pulmonary artery and prominent left atrium. The cardiothoracic ratio was 0.61. A clinical diagnosis was made of a leaking xenograft with pulmonary edema, pulmonary hypertension and right heart failure.

Laboratory tests revealed a blood hemoglobin level of 13 g/dl and an erythrocyte sedimentation rate of 3 mm in 1 hour. Results of the white cell count, urea and electrolyte determinations, urine analysis, blood cultures, serum complement and serum calcium measurements were normal.

Urgent mitral valve replacement was undertaken because of recurrent episodes of pulmonary edema that did not respond to medical therapy. At operation, the xenograft was stenosed and admitted only the tip of the index finger; the cusps were heavily calcified and their rigidity was greatly increased. No evidence of mitral regurgitation was noted. The valve was removed and replaced with a 31 mm Carpentier-Edwards xenograft.

Case 2

A 13 year old Indian girl had mitral valve replacement with a 29 mm glutaraldehyde-preserved Carpentier-Edwards xenograft for severe rheumatic mitral incompetence. Her postoperative course was uneventful and on regular follow-up visits to the cardiac clinic there was no evidence of intervening infective endocarditis, and no murmurs were audible. She was well until 25 months after operation when she reported the sudden development of dyspnea on exertion and orthopnea of 2 weeks' duration.

On examination, she was apyrexial, with no pallor or clubbing. The pulse rate was 100/min and regular, blood pressure was 100/80 mm Hg, the jugular venous pressure was elevated at 7 cm with prominent *a* waves and the apex beat was palpable in the fifth intercostal space at the mid clavicular line. A right ventricular left parasternal impulse was present and at the mitral area a diastolic thrill and a long grade 4/4 rumbling diastolic murmur was heard. The pulmonary component of the second heart sound was accentuated. At the tricuspid area a grade 2/6 pansystolic murmur increasing on inspiration was audible.

An electrocardiogram revealed sinus rhythm (rate 100/min), P pulmonale, a QRS axis of +120° and marked right ventricular hypertrophy. The findings 6 months previously showed no P pulmonale and an axis of +60°. The chest X-ray film demonstrated a cardiothoracic ratio of 0.68 and a very prominent pulmonary arterial, left atrial and right ventricular segments compared with findings in a film obtained 6 months previously. The hemoglobin level was 12.6 g/dl and the erythrocyte sedimentation rate 8 mm in 1 hour. The serum calcium was normal.

Cardiac catheterization (*Table I*) revealed severe stenosis of the xenograft with a mitral valve area of 0.5 cm^2 and severe pulmonary hypertension. *Left ventricular angiography* revealed a small left ventricle with good contractility and very little blood crossing the xenograft. *The patient required emergency mitral valve replacement* immediately after catheterization because of severe decompensation. At operation the three cusps of the xenograft were grossly calcified, and there was only a pinhole central orifice. A 29 mm Hancock xenograft was inserted.

Case 3

A 14 year old African girl had mitral valve replacement with a 29 mm Carpentier-Edwards xenograft for rheumatic mixed mitral valve disease. Her postoperative course was uneventful and she made regular follow-up clinic visits; there was no intervening history of, or treatment for, infective endocarditis. No abnormal murmurs were detected in the follow-up period. Seventeen months after mitral valve replacement orthopnea and extreme tiredness developed. The symptomatic disability had occurred abruptly and was of only 1 week's duration.

On examination, no pallor, clubbing or fever was found. She had tachycardia (rate 120/min) and a pulse of small volume; jugular venous pressure was elevated at 8 cm and the apex beat was tapping in character in the fifth intercostal space. A right ventricular left parasternal impulse was present. A grade 3/6 pansystolic murmur increasing with inspiration was present at the apical area; no diastolic murmur was audible.

An electrocardiogram revealed a frontal QRS axis shift from +60° to +120°, and a markedly enlarged left atrium compared with findings in an electrocardiogram obtained 3 months earlier. The chest X-ray film demonstrated a cardiothoracic ratio of 0.62 with increased left atrial, pulmonary arterial and right ventricular segments compared with those observed in films obtained 6 months earlier. The hemoglobin level was 11 g/dl, and the erythrocyte sedimentation rate was 7 mm in 1 hour; the white cell count and serum calcium levels were normal.

Cardiac catheterization (*Table I*) revealed stenosis of the xenograft with a calculated valve area of 0.4 cm^2 and marked pulmonary hypertension. A left ventricular angiogram demonstrated a small, well contracting left ventricle with very little

TABLE I

Cardiac Catheterization Data

	Case 2	Case 3
Pressures (mm Hg)		
Right atrium	10	16
Right ventricle	90/7–14	110/4–10
Pulmonary artery	90/45 *mean 60*	120/70 *mean 87*
Pulmonary capillary wedge	38; *a* 40; *v* 38	44; *a* 50; *v* 48
Aorta	100/60 *mean 73*	105/78 *mean 87*
Left ventricle	100/0–8	105/0–8
Mitral mean diastolic gradient	28	33
Pulmonary capillary wedge end-diastolic gradient	28	30
Mitral valve area (cm^2)	0.5	0.4
Cardiac output (liters/min)	2.4	1.8

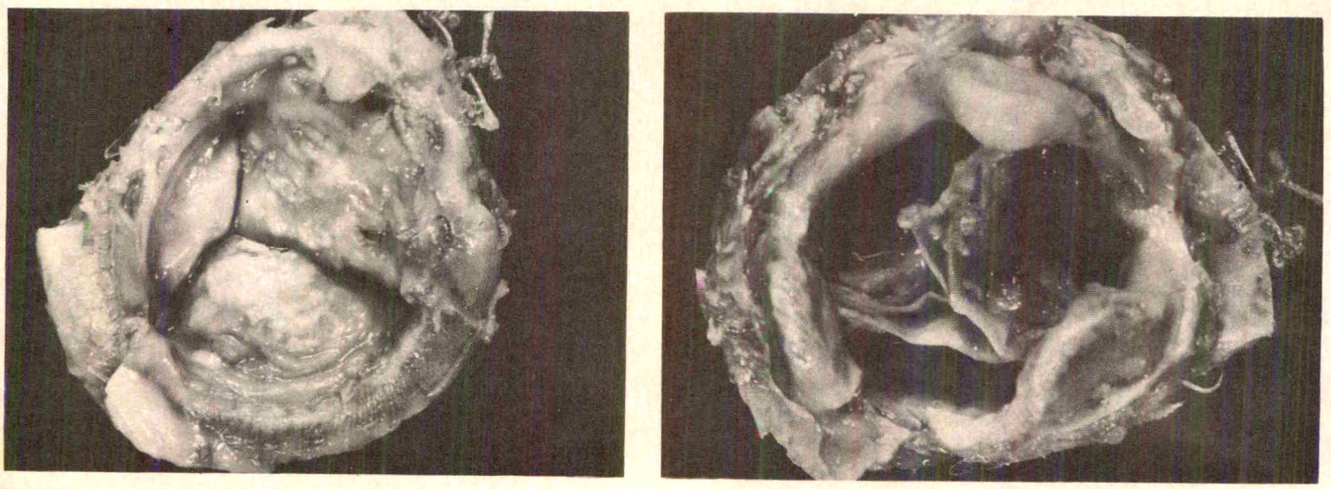

FIGURE 1. Case 3. **Left,** atrial surface of glutaraldehyde-preserved Carpentier-Edwards xenograft showing severe calcification. There is a small traumatic laceration on right upper cusp. **Right,** ventricular surface of the xenograft showing extensive nodular calcification with fusion of cusps and a virtually nonexistent orifice.

blood crossing the xenograft. After catheterization, the patient needed respiratory and cardiac support because of a severe low output state and respiratory distress.

Emergency mitral valve replacement was undertaken. At operation the xenograft was found to be extensively calcified with a pinhole central orifice (Fig. 1). The xenograft was removed and replaced with a 29 mm Hancock xenograft.

Case 4

A 14 year old African boy had mitral valve replacement with a 31 mm glutaraldehyde-preserved Hancock xenograft for severe rheumatic mitral incompetence. His postoperative course was uneventful. He was well until 19 months after the operation when he presented with swelling of the legs and dyspnea on exertion of 1 week's duration.

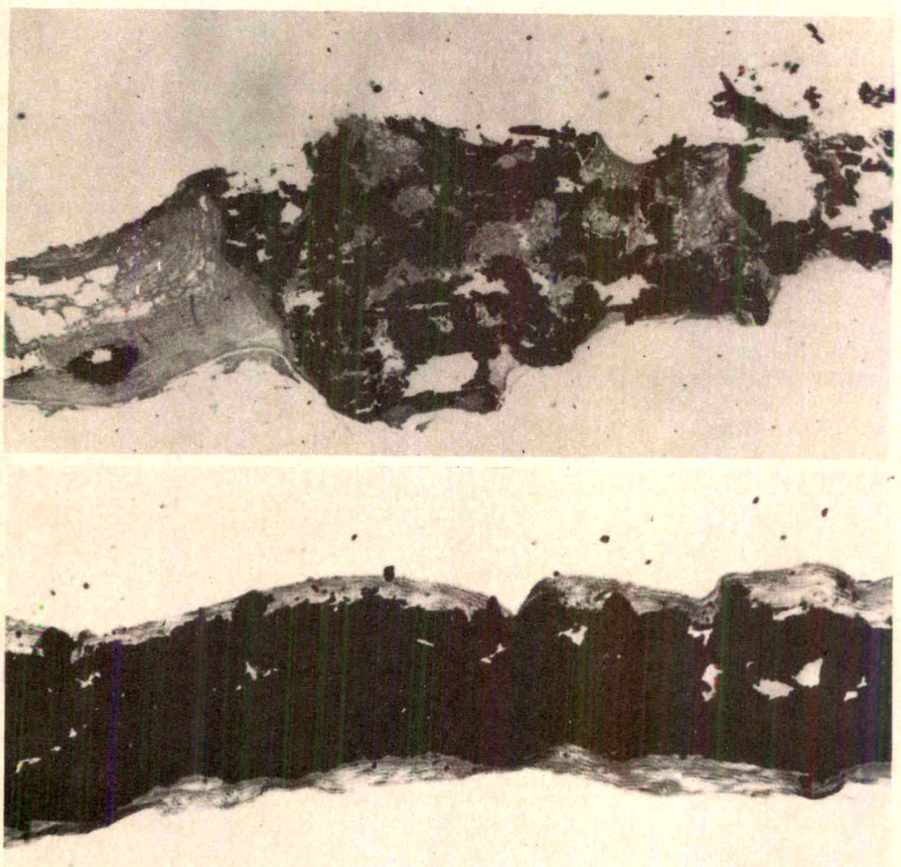

FIGURE 2. Top, Case 2. Xenograft cusp showing focal calcification resulting in nodular thickening. **Bottom,** Case 3. Xenograft cusp demonstrating central linear calcification without thickening of the cusp. (Von Kossa ×70 [**top**] and ×200 [**bottom**].)

On examination, the pulse was of small volume at 100/min and regular and the jugular venous pressure was elevated at 6 cm. The left parasternal impulse was right ventricular in type. A short grade 1/4 mid diastolic murmur was present at the mitral area and a grade 2/6 pansystolic murmur was audible at the tricuspid area.

An electrocardiogram, when compared with the record obtained 6 months previously, showed a shift of the mean frontal QRS axis from 0° and 90° and left atrial enlargement; the chest X-ray film demonstrated left atrial and right ventricular enlargement.

At operation, the Hancock valve was found to be grossly calcified with fenestration of one of the leaflets. The bioprosthesis was removed and replaced with a size 31 mm Hancock xenograft.

Operative Techniques

The original operative technique in each case was similar, with use of cardiopulmonary bypass at normothermia. Before implantation, the bioprosthesis was rinsed three times in a sterile saline solution for 5 minutes in each rinse. Venting was achieved using a size 24 French angled Argyle cannula that was passed through the left atriotomy and implanted valve into the left ventricular cavity. The vent was maintained in this position for approximately 10 minutes in each case.

Cardiac Pathology and Histology

The valve cusps were extensively calcified in all four cases. In one cusp a continuous band of calcification was present throughout its length, but in others deposition was focal with intervening uncalcified portions. In some areas the calcification was heavy, resulting in nodular thickening (Fig. 2, top); elsewhere it was linear and centrally located without apparent thickening of the cusp (Fig. 2, bottom). The appearances, particularly of the nonthickened portions, suggested dystrophic calcification rather than calcification of overlying thrombosis.

Donor heart muscle was present at the base of one cusp in three cases. Dystrophic calcification of muscle fibers was marked in two of these cases but minimal in the third (Fig. 3).

Surface thrombus was present in two cases (Cases 1 and 4). In Case 1, foci of calcification (Fig. 4, left) were present in the thrombus, and the opposite side of the cusp showed a mixed inflammatory infiltrate in the superficial layers (Fig. 4, right). The infiltrate consisted of lymphocytes, neutrophils, macrophages and eosinophils; its significance is not known. Inflammatory cells were not present in the thrombus. No evidence of inflammation was found in the other three cases.

Electron microscopy of a portion of one of the cusps in Case 4 (Fig. 5) showed groups of collagen fibrils in amorphous material that presumably represents products of collagen degeneration.

Discussion

An ideal preservative agent for stabilization of xenografts should guarantee sterilization and eliminate antigenic components, thus preventing host immune reaction and promoting strong, irreversible cross-linking of collagen molecules to prevent collagen degeneration and maintain architectural integrity. These features enhance durability. Reports of several series[2,4,7] have described greater durability of xenografts preserved with glutaraldehyde as opposed to formalin. This has been ascribed mainly to the superior fixation process with glutaraldehyde, which provides stronger cross-linkage of collagen molecules and less tissue antigenicity.[3,16]

Glutaraldehyde-preserved, mounted aortic porcine xenografts are considered safe and effective bioprostheses in the mitral valve position. Adequate hemodynamic function is obtained, there is a small incidence of thromboembolism without anticoagulation and reports[3] of short- and medium-term durability are good.

In our institution, the glutaraldehyde-preserved porcine xenograft has been the prosthesis of choice for valve replacement, and 400 have been implanted over the past 5 years. The four cases of severe calcification reported here occurred only over the last 18 months and represent 1 percent of the total number of implanted prostheses.

Clinical presentation: Our four cases were characterized by the acuteness of the presentation and lack of symptoms until onset, absence of auscultatory evidence of mitral stenosis in some cases, youth of the patients and pathologic features of the valves.

The pattern of deterioration and clinical presentation of the four patients was interesting. Mild and moderate stenosis appeared to cause minimal symptomatic disability, if any; however, when severe symptoms developed, the onset was acute and related to critical stenosis. Clinical deterioration was rapid, taking the form of a low output state and episodes of pulmonary edema in the presence of pulmonary hypertension and right heart

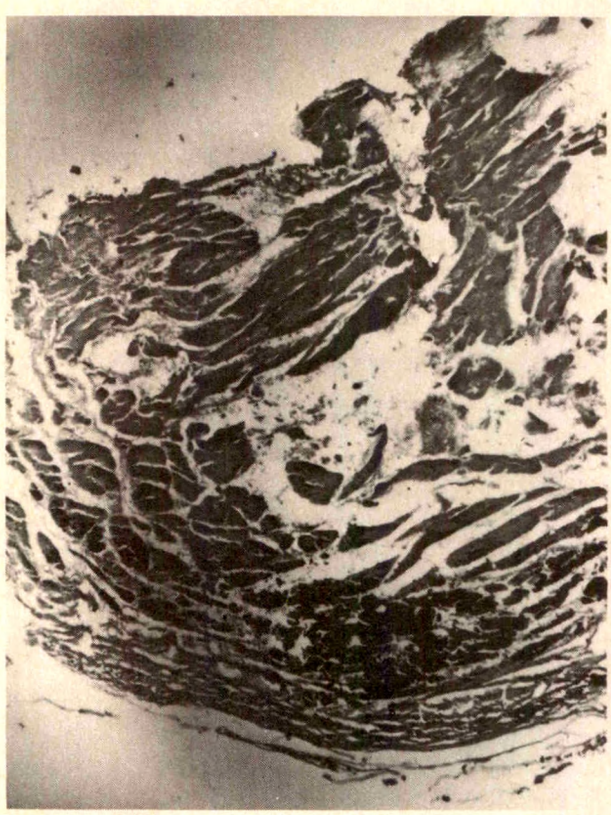

FIGURE 3. Case 4. Donor heart muscle at base of one cusp of the xenograft showing calcification of muscle. (Von Kossa ×200.)

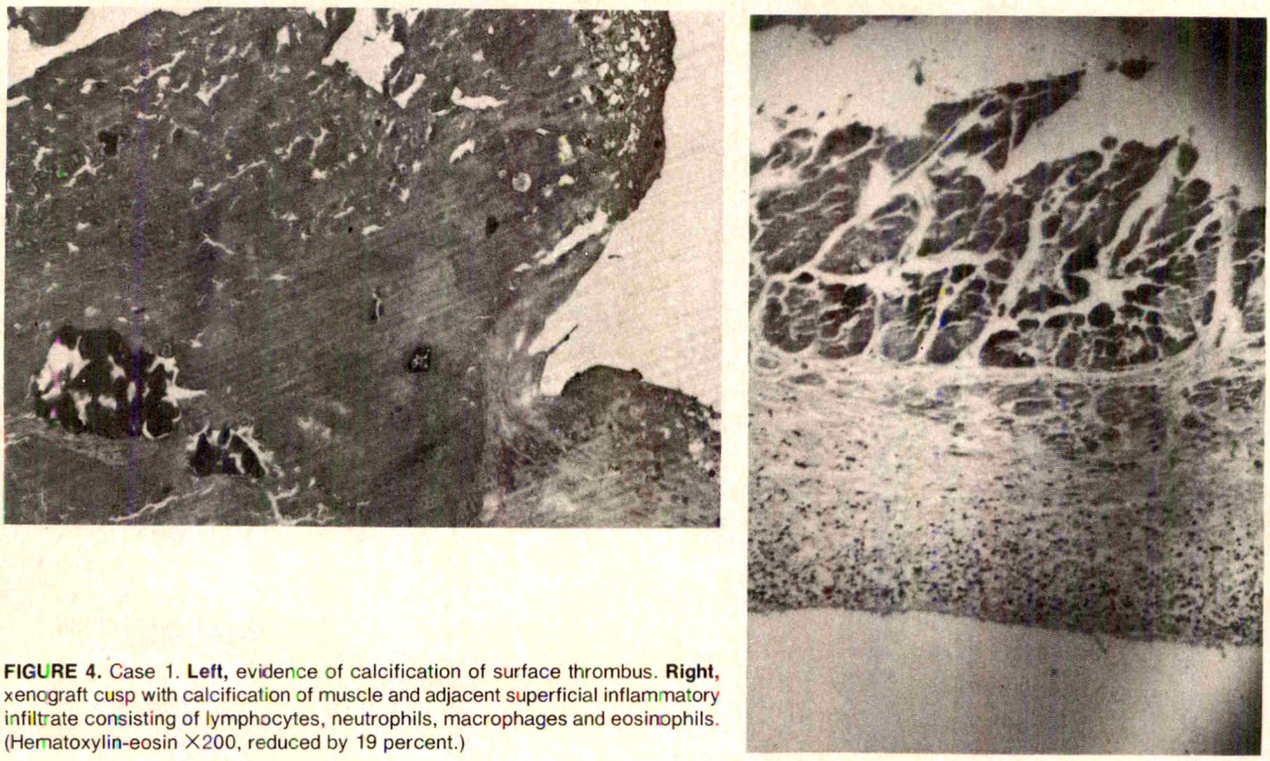

FIGURE 4. Case 1. **Left,** evidence of calcification of surface thrombus. **Right,** xenograft cusp with calcification of muscle and adjacent superficial inflammatory infiltrate consisting of lymphocytes, neutrophils, macrophages and eosinophils. (Hematoxylin-eosin ×200, reduced by 19 percent.)

failure necessitating urgent mitral valve replacement. Cardiac catheterization data vividly illustrate the poor hemodynamic status and severity of the pulmonary hypertension.

Previous reports have usually described xenograft deterioration as gradual, with elective operation under optimal conditions being advocated. In the reported cases, valve failure has usually been secondary to regurgitant lesions. Our cases highlight the possibility that when obstructive lesions develop, emergency surgery may be necessary.

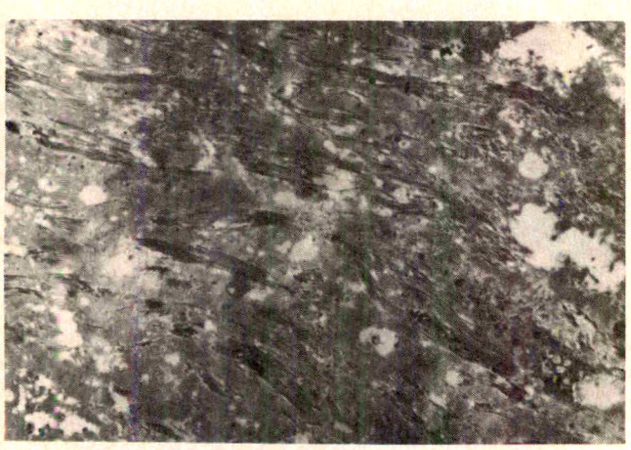

FIGURE 5. Case 4. Electron micrograph of a portion of a xenograft cusp showing collagen fibrils in amorphous material. (×4,000.)

Diagnosis of valve dysfunction: The absence of auscultatory evidence of mitral valve dysfunction and misinterpretation of murmurs in some cases of glutaraldehyde-preserved porcine xenograft with stenosis deserves comment. In two patients, repeated auscultation failed to reveal any evidence of a mitral diastolic murmur, and in the third patient only a short diastolic murmur was present, in spite of the existence of severe stenosis. This unusual finding can be explained by examination of the left ventriculograms in the two patients who underwent catheterization. In both cases, flow across the bioprosthesis was minimal, in keeping with the low cardiac output.

Auscultation alone may be unhelpful and difficult in the diagnosis of stenotic xenografts in the mitral valve position. Forfar et al.[14] experienced this problem immediately postoperatively in their patient who underwent aortic and mitral valve replacement with xenografts. They noted no auscultatory evidence of mitral valve dysfunction despite the presence of severe stenosis of the mitral xenograft. Furthermore, they misinterpreted a murmur of pulmonary regurgitation as aortic regurgitation and incorrectly believed that the patient needed aortic valve replacement.

In our Case 1 we misdiagnosed a leaking xenograft. The murmur of tricuspid regurgitation may be well heard at the apical area because of right ventricular hypertrophy and rotation anteriorly and, in the absence of a mitral mid diastolic murmur, as described, it is easy to arrive at an auscultatory misdiagnosis of a leaking xenograft.

Other diagnostic features used in conjunction with clinical findings include electrocardiographic evidence of rightward shift of the mean frontal QRS axis and radiologic signs of increasing left atrial and pulmonary arterial segments in the chest X-ray film. Although echocardiography was not performed in any of our cases, this investigation may provide valuable early information on stenotic prosthestic valve dysfunction. Alam et al.[17] described M mode features of porcine valve stenosis as consisting of increased cusp echoes and loss of normal cusp detail. Others[18,19] have described a reduction in the initial diastolic slope of the porcine stent.

Age and race: All four patients were young, with a mean age of 14 years. The patients described by Forfar[14] and Rose[15] and their co-workers were also young: 12 and 26 years, respectively. From the age of all the patients involved, it appears that accelerated calcification of glutaraldehye-preserved porcine xenografts may be a more common occurrence in the young person. Hence, the implication is that the glutaraldehyde-preserved porcine xenograft may not be the ideal prosthesis in the young person.

Two of our patients were Indian and two were African; the patient described by Forfar et al.[14] was white. The small number of cases does not allow any valid conclusion relating to racial predilection.

Incidence of early valve calcification: Severe early calcification of glutaraldehyde-preserved porcine xenografts in the mitral valve position has been extremely rare. Only two cases have previously been reported: one, described by Forfar et al.,[14] of severe microscopic calcification of a Carpentier-Edwards bioprosthesis within 19 days of implantation, and the other, described by Rose et al.,[15] of severe calcification in a Hancock bioprosthesis removed at autopsy 12 months after implantation.

Collagen degeneration as a cause of calcification: The striking feature of our cases is the severe calcification of these xenografts and relatively short interval from implantation to calcification. Furthermore, no patients had any disturbance of calcium metabolism or previous infective endocarditis. The histologic features strongly suggest dystrophic calcification from primary heterograft failure, that is, primary collagen degeneration. Carpentier et al.[20] reported that denaturation of collagen after several years appeared to be a major problem, but the alarming feature in all of our cases was the severe degeneration of collagen occurring relatively early, at a mean duration of 19 months.

A further feature in three of our cases was the total absence of immunocompetent or inflammatory cells in the presence of collagen degeneration and severe calcification. Spray and Roberts[21] described inflammatory cells or immunologically competent cells, or both, in more than 70 percent of their grafts removed 2 to 25 months after implantation. Their two cases with severe disruption of cusp tissue demonstrated only a few giant cells despite the presence of collagen degeneration and calcification. The absence of a cell infiltrate in our three cases may be related to primary collagen degeneration itself, as previously described by Carpentier et al.[20]

The exact cause for collagen degeneration and accelerated calcification of these prostheses is unclear, although increased calcium turnover or immunologic factors, or both, may play a role. Additional follow-up series are needed to assess the etiology and magnitude of this problem.

Acknowledgment

We are grateful to Denise Ferreira for secretarial assistance, and to David Nathan, MD, for criticism.

Addendum

Since submission of this manuscript, a further six children (age range 11 to 16 years; mean 13) and one adult (22 years) have presented with severely calcified glutaraldehyde-preserved porcine xenografts in the mitral valve position. The duration from implantation to severe calcification has ranged from 18 to 36 months (mean 26). Four of these were Carpentier-Edwards valves and three Hancock xenografts. Further, Kutsche et al.[22] recently reported findings in nine children who underwent mitral valve replacement with a Hancock glutaraldehyde-preserved porcine xenograft. In three of the nine severe fibrocalcification of the prosthesis developed within 3.5 to 4.8 years of implantation.

These findings tend to confirm our earlier impression that early calcification of these prostheses is a complication in children and that the glutaraldehyde-preserved porcine xenograft is not the prosthesis of choice for mitral valve replacement in children. Further follow-up studies are needed to assess the suitability of this prosthesis in young adults because one patient in this series was 22 years old and the patient reported on by Forfar et al.[14] was 26 years old.

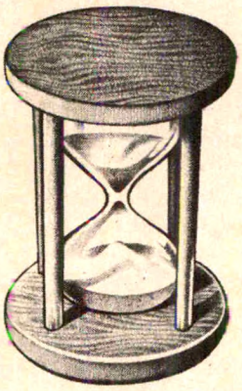
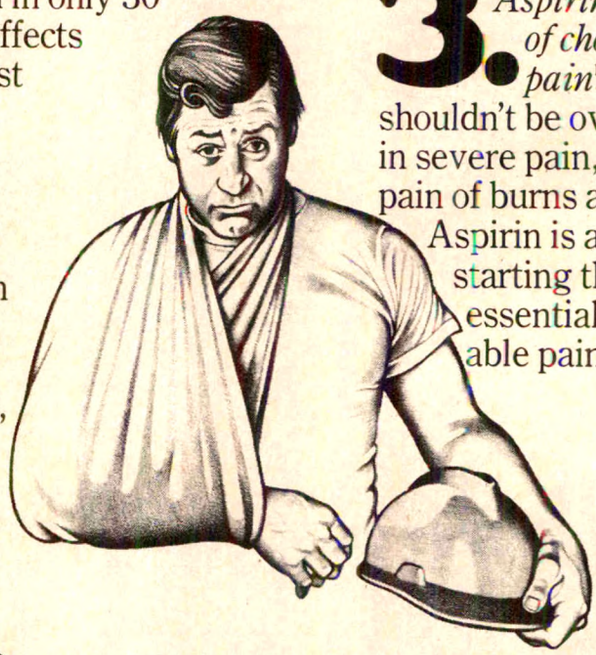
10 reasons why medicine's most analgesic

1. *Aspirin is the prototype among analgesics/antipyretics.*[1] It continues as the standard for non-narcotic analgesic efficacy[2]...effective against most types of pain.



2. *Aspirin acts quickly and predictably.* Following ingestion, appreciable plasma levels are reached in only 30 minutes or less.[2] Effects of a single dose last 4-6 hours.[3]

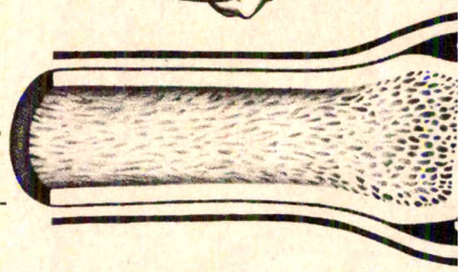
3. *Aspirin is the drug of choice for mild pain*[1]...but its use shouldn't be overlooked in severe pain, such as the pain of burns and trauma.[1] Aspirin is appropriate starting therapy for essentially all treatable pain problems.[5]

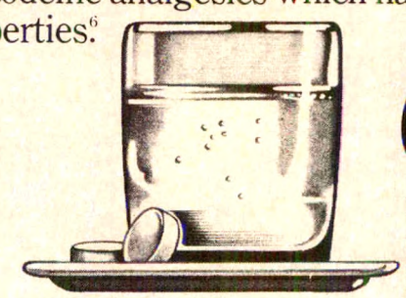


4. *Aspirin is preferable to narcotics* when practical, since much pain is chronic and recurring.[1] However, even when narcotics are required, concomitant use of aspirin may permit smaller-than-usual doses of the potentially dependence-producing agent.[1]

BAYER + COD + CKER

5. *Aspirin is basic anti-inflammatory therapy.* This action makes it much more useful for inflammatory conditions, such as rheumatoid arthritis, than acetaminophen, propoxyphene or codeine analgesics which have no anti-inflammatory properties.[6]



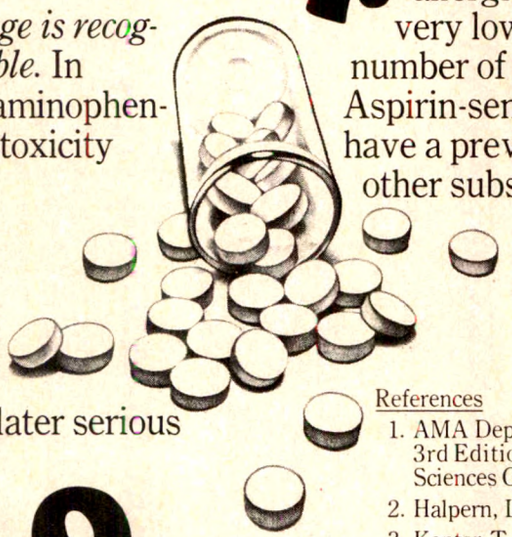


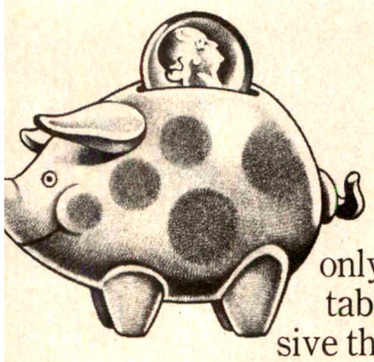
6. *Aspirin has a highly favorable benefit-to-risk ratio.* Aspirin ranks as one of medicine's best-tolerated drugs.[5,7] Serious adverse reactions are infrequent with usual analgesic doses.[1]

aspirin is still widely used

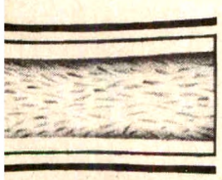
7. *Aspirin has a low potential for allergic reactions.* The incidence of allergic reactions to aspirin is very low considering the vast number of tablets taken each year.[8] Aspirin-sensitive patients will usually have a previous history of allergy to other substances.[9]

8. *Aspirin overdosage is recognizable, treatable.* In contrast, acetaminophen-induced hepatotoxicity hat may result from verdosage is much ess amenable to herapy...and ariable early symp-oms may not be ccurately predictive of later serious omplications.[10]





9. *Aspirin is inexpensive.* Aspirin still costs patients only about a penny per tablet. It is less expensive than most commonly used drugs for pain and a great deal less expensive than the newer non-steroidal antiarthritic agents.



10. *Aspirin is unique.* No analgesic, no antipyretic, no anti-inflammatory agent an match its broad clinical versatility, ts almost 80 years of experience or ts outstanding record of therapeutic ffectiveness.

$33.00 SEPTEMBER 1978, 288 PAGES, 110 ILLUS, 1,000 REF.

Every Cardiologist, Internist, Pediatrician, Surgeon — Indeed, *Every Physician* — Should Have a Good Basic Knowledge of The Pre-excitation Syndrome. Here Are Just a Few Reasons Why This is so Essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

The 13 Chapters Are a Comprehensive Summary

1. General Considerations
2. The Electrocardiogram in the Pre-excitation Syndrome: Complexes and Configurations
3. The Electrocardiogram in the Pre-excitation Syndrome: Disturbances of Rate and Rhythm
4. Pathology
5. Noninvasive Methods of Investigation
6. Invasive Methods of Investigation
7. Prognosis
8. Treatment
9. Problems of Diagnosis — Some Illustrative Cases
10. Summary of Findings and Theories of Pre-excitation Syndrome
11. Concept of Interacting Structural and Functional Factors
12. Explanation of Some Phenomena of the Pre-excitation Syndrome by the Proposed Concept
13. Various QRS Patterns in the Different Forms of Pre-excitation

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals

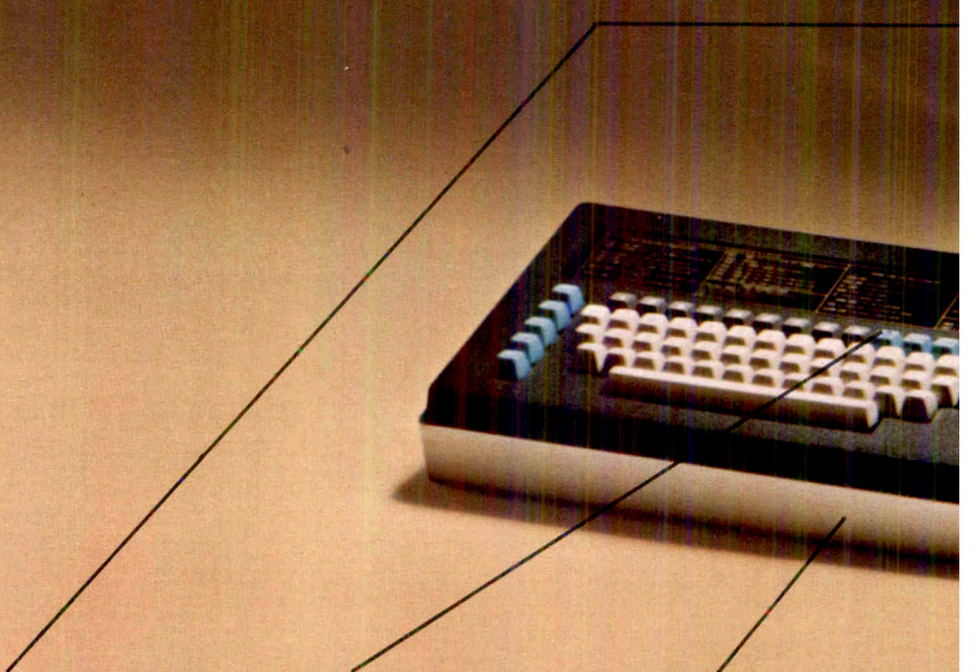
HAVE M.A.D. COLOR
VIDEO DATA SYSTEMS
FOR YOUR I.C.U.-C.C.U.
NURSE'S STATION
MIDWEST ANALOG & DIGITAL
Howard Young Medical Center 16 Bed I.C.U.-C.C.U., Woodruff, Wisconsin

HERE'S PROOF THAT M.A.D. DELIVERS MORE FOR LESS THAN ANY OTHER SYSTEM!



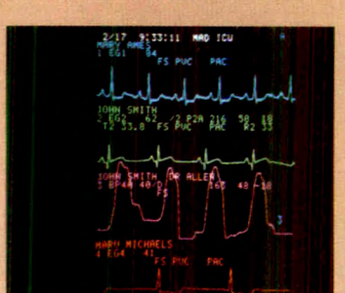
Never Obsolete! The originally installed equipment always remains the same. Only the program need be inexpensively changed if you want to update your present capabilities.

Connects with any bedside equipment you already have or wish to change to in the future. Connects with little or no modification of either our system or your bedside equipment.

Works independently of readouts and alarms of bedside equipment to give you a double check of accuracy.

Cursor feature provides opportunity for waveform examination: time intervals within ECG's and pressure traces; specific values of pressures or trends; mean, maximum and minimum values of pressures within selected intervals.

Color coded, non-fade patient trace, numbers, and text all shown on the same screen.

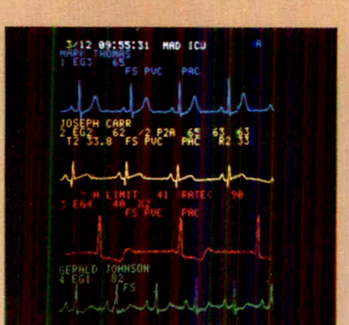


Displays ECG's, multiple blood pressures, temperatures, respiration, cardiac output, arrhythmia rate and trend, for each patient, coded in color, all on the same screen.

Special automatic arrhythmia recording is assignable to any and all patients.

Alarm interrupts both manual and automatic recording. Equipment resumes original recording after alarm.

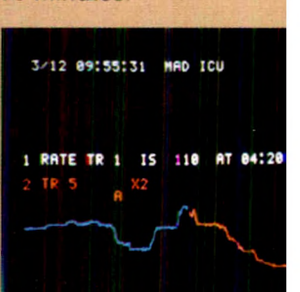
High *and* low alarm thresholds digitally set for *all* parameters.



Shows *both* alarms and near alarms in different special colors independent of bedside equipment.

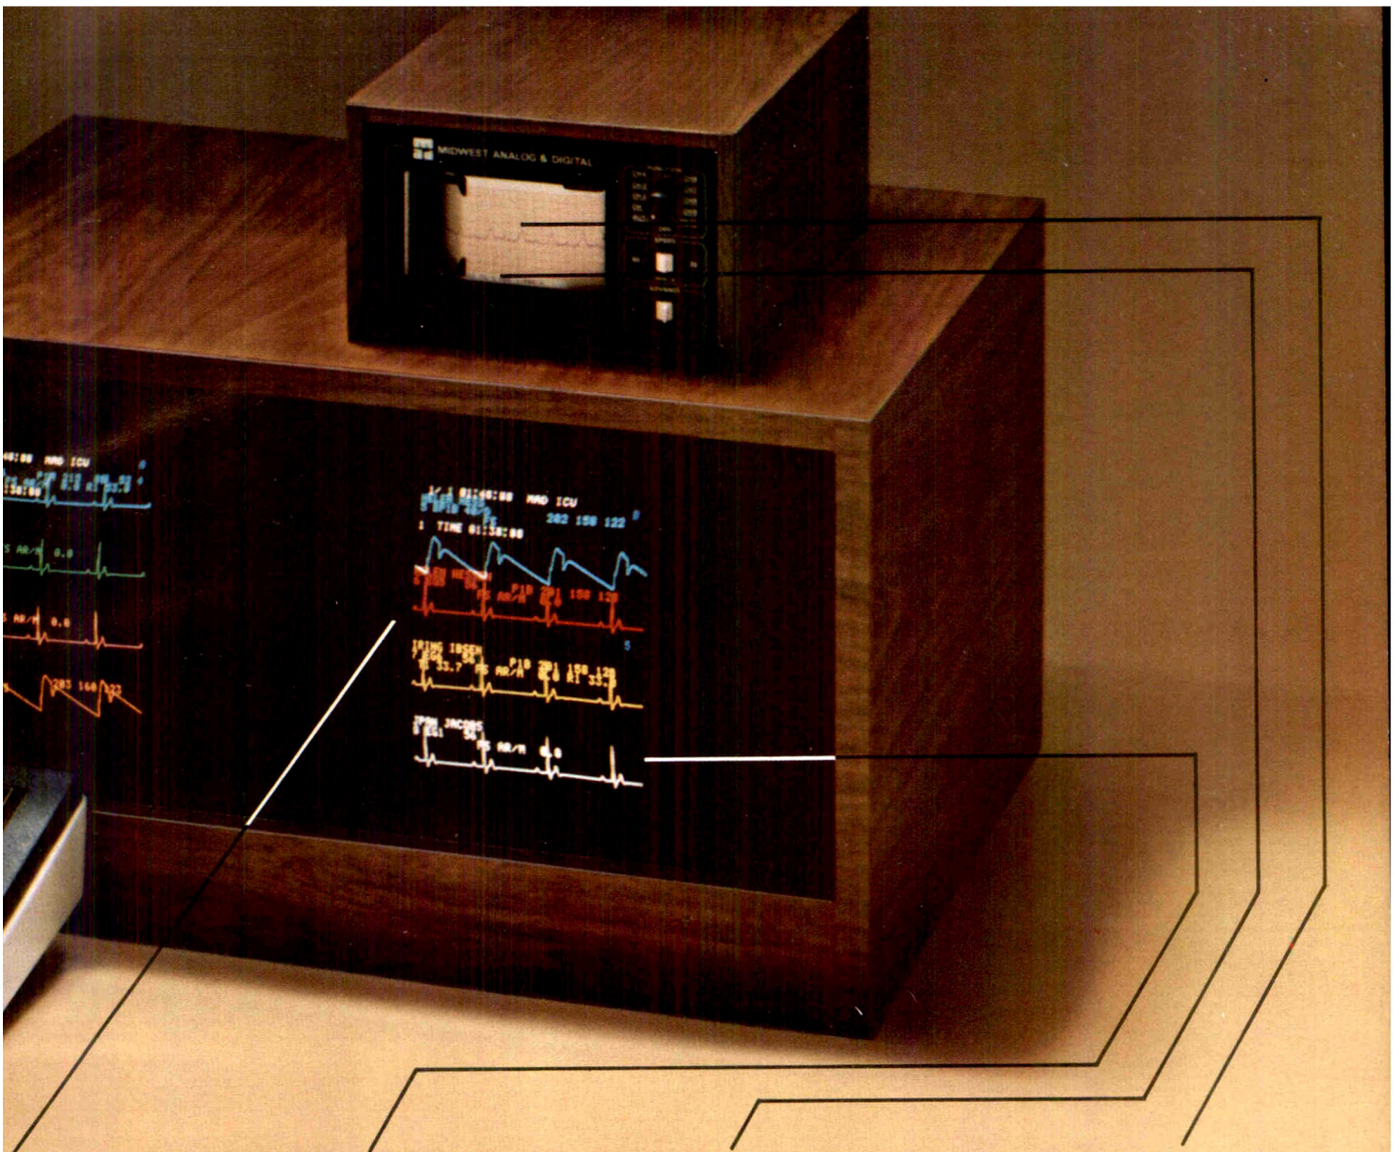
Alarm gives you special alarm colors, flashing readout, audible alarm and automatic chart recording. Standby mode does not shut off alarm color change.

Easy to use keyboard. Lo
like a typewriter. Works
a hand calculator. Work
knowledge can be gaine
15 minutes.

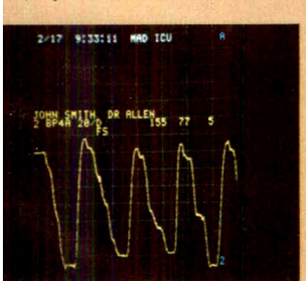


Trending, both short and l
term is fully automatic
versatile. Done on all par
eters, analyzed with di
precision and hard copie

The screen shows you ev
thing! You can get accu
readings of the Systolic,
astolic and Mean pressu
from a screen for any an
patients all the time.



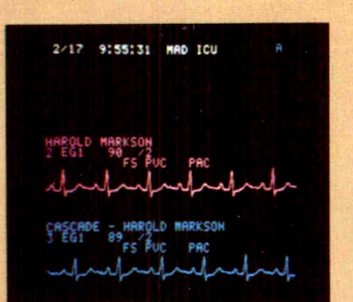
to 8 parameters and 8 ital readouts per channel y be assigned to any pa- nt. Can examine up to 64 rameters and readouts on r typical two screen (8 pa- nt) system.



curate grid may be dis- ayed behind traces for visu- confirmation of calibrations.

aces can be enlarged or re- ced or positioned any- ere on the screen. Calibra- n and baseline identifi- tion are never lost even ough traces are manipu- ed.

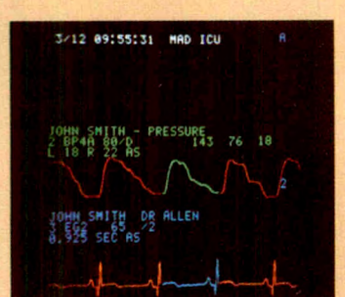
Clean, simple display. Only the required data need be displayed.



Any trace, including pressures, can be cascaded to any other available screen space. Color coding is automatic.

The M.A.D. system is a preprogrammed computer system customized to fit your needs. It is lower in price than non-computerized systems of far less capability that are limited in their ability to be updated without adding more modules.

Automatically prints patient's name, doctor's name, time and date onto chart recording. All parameter values for that patient are also printed. Annotates every ten seconds with up-to-date printed readouts while recorder is running . . . all independent of bedside equipment.



Calculations and analysis may be done on any portion of a frozen waveshape by cursors (color, pointers or vertical lines). ECG's and pressures may be frozen together for comparison.

ECG, pressure, or other waveforms, even trends can be strip recorded manually or automatically.

Since the M.A.D. system is computerized and not hardwired, the nurse can assign any of these features to any bed, collect patient data from remote locations, interconnect to other nurse's stations . . . this allows maximum use of the system at all times. Eliminates the need for additional modules and additional staff.

You don't buy anything you don't need or will use only infrequently. Everything you purchase is put to practical use.

Only M.A.D. gives you all this capability in a four square foot area.

MIDWEST ANALOG & DIGITAL INC.

JUST ANOTHER MONITORING SYSTEM?

NOT WITH M.A.D.

Midwest Analog & Digital, Inc. was created by doctors and engineers to present patient monitoring systems that, for the first time, give you everything you require at an affordable price. A system that never becomes obsolete . . . that will never require a hardware change . . . that can be updated at anytime . . . that provides functions you could only wish for before . . . that puts the nurse back at the bedside . . . that allows doctors research capability without additional expense . . . that assures biomedical engineers of minimum maintenance.

Installations are available across the country for your viewing or we will provide demonstrations in your area a your request. M.A.D. has the only monitoring system tha can be customized to meet your exact needs without additional modules or extra cost.

Around-the-clock service as near as your telephone.

Just call your local area M.A.D. representative. M.A.D. provides factory trained service representatives at any time of the day or night.

5 YEAR WARRANTY

An industry first! The advanced technology, rigid quality controls and five year in-use field testing of the M.A.D. ICU/CCU System in Hospitals throughout the country allow us to give you the most comprehensive Warranty in the market. This also assures you of the superior quality of the M.A.D. Color Video Data System*

*See us or your M.A.D. Representative for complete Warranty details.

We don't stop at coronary care and intensive care.

Silent Myocardial Ischemia in Patients With a Defective Anginal Warning System*

PETER F. COHN, MD, FACC

Boston, Massachusetts

The syndrome of silent myocardial ischemia is a subject of continuing controversy. Although some physicians doubt that it is possible to have myocardial ischemia without anginal symptoms, most physicians believe it occurs but are unsure of its prevalence and clinical significance. Because angina may be regarded as a warning to stop an activity before there is further potentially fatal damage to the myocardium, patients who do not experience it during myocardial ischemia—or whose symptoms are so trivial as to be disregarded—may be thought of as having a *defective anginal warning system.* The defect may be considered *incomplete* in patients whose ischemic episodes are occasionally symptomatic and *complete* in patients who never experience angina.

In discussing this syndrome, two assumptions need to be made. The first assumption is that there are objective indicators of myocardial ischemia that can be evaluated in clinical studies and correlated with the presence or absence of symptoms. This assumption appears valid. Generally accepted indicators of myocardial ischemia include stress-induced abnormalities of left ventricular wall motion, myocardial perfusion and lactate metabolism in regions subserved by stenosed coronary arteries. In the absence of symptoms, there is perhaps less agreement concerning the reliability of certain electrocardiographic indicators of myocardial ischemia such as S-T segment abnormalities and ventricular arrhythmias. The second assumption is that the history taken accurately reflects the absence of angina pectoris or its usual equivalents in the particular patient. The validity of this second assumption rests mainly on the many studies (to be cited subsequently) from different centers involving a large number of experienced cardiologists who would be expected to be reliable historians.

From the Cardiovascular Division, Department of Medicine, Peter Bent Brigham Hospital and Harvard Medical School, Boston, Massachusetts. Manuscript received August 20, 1979; revised manuscript received and accepted November 20, 1979.

Prevalence of Silent Myocardial Ischemia in Symptomatic Persons

The prevalence of this syndrome in symptomatic patients is unknown, but it appears to occur more commonly than is generally appreciated. Some estimate of its frequency can be obtained by reviewing the published studies dealing with the abnormalities of myocardial function. Pertinent representative studies are summarized in Table I and commented on more fully in the subsequent sections.

Regional abnormalities of ventricular wall motion: The initial studies in this area were performed with contrast ventriculography. Myocardial ischemia was induced by means of rapid atrial pacing. The end point was either angina or, in its absence, S-T segment abnormalities or a target heart rate. The control and stress ventriculograms were then compared for evidence of new abnormalities of wall motion or worsening of prior abnormalities. For example, in the study by Dwyer,[1] three (38 percent) of eight patients with coronary artery disease who exhibited these abnormalities had no symptoms but did have associated S-T segment depression. In another study,[2] six (76 percent) of eight patients had no symptoms and five of the six had S-T segment depression. The bicycle ergometer has also been used to precipitate left ventricular dysfunction during contrast ventriculography[3] and echocardiography,[4] but relevant data concerning wall motion changes and anginal symptoms are not clearly specified in these reported studies. More information is available from studies combining bicycle exercise with radionuclide ventriculography. Borer et al.[5] did not elicit angina in 18 (29 percent) of 63 patients who had regional dys-

function during this type of test, whereas in a smaller series[6] of patients in the postinfarction state, 6 (75 percent) of 8 were free of angina.

Abnormal lactate metabolism: Normally, the heart does not produce lactate, but it may do so during myocardial ischemia. This can be demonstrated clinically with a catheter positioned in the coronary sinus. The catheter serves a dual purpose: to pace the heart to ischemia and to sample coronary sinus blood for lactate levels. Because the coronary sinus effluent is largely from the area subserved by the left coronary artery, abnormal lactate metabolism reflects myocardial ischemia when that vessel system is diseased. In such patients, the prevalence of lactate abnormalities without anginal symptoms has ranged from 1 (7 percent)[7] of 14 to 8 (36 percent) of 22.[8]

Myocardial perfusion defects: The demonstration of new defects in scintigrams performed during exercise with potassium-43 or its analogs is considered evidence of myocardial ischemia in the presence of coronary artery disease. Many, but not all, such defects are associated with S-T segment changes. In one study,[9] 20 (57 percent) of 35 patients with angiographically proved coronary artery disease and new defects on thallium-201 exercise scanning reported no exercise-induced angina; in another study,[10] 6 (19 percent) of 29 patients with abnormal rubidium-81 exercise scintigrams did not have angina during the exercise.

Electrocardiographic abnormalities: Several groups have commented on the absence of angina or its equivalents during or after exercise tests showing ischemic (flat or downsloping) *S-T segment depression* in patients with angiographically defined coronary artery disease. Although the exercise techniques and definitions of anginal equivalents are not necessarily identical, these figures nevertheless provide an indication of how frequently this finding is observed. In the five studies[11–15] cited in Table I, 32 percent of the p itive exercise tests were not associated with angi symptoms. This is very similar to the 36 percent i dence rate found during abnormal ventricular v motion, lactate and myocardial perfusion studies suggests that these electrocardiographic findings indeed reliable. In one of the two studies from the Pe Bent Brigham Hospital,[13] clinical, hemodynamic angiographic features in the patients with and with angina on exercise testing were compared. Some of th features included prior history of myocardial infarct hyperglycemia, taking of various cardiac medicati such as digitalis and propranolol, depth of S-T segm depression on exercise and frequency of multive disease. No significant differences between the groups were found. However, other workers have ported a greater frequency of multivessel disease in patients with test-induced angina.[11,14]

Ambulatory electrocardiographic monitoring n also reveal painless episodes of S-T segment depress in patients with coronary artery disease. Despite c cern about the reliability of lesser grades of S-T segm depression observed with this technique, the ambu tory electrocardiogram does provide additional d concerning the prevalence of silent myocardial ischer For example, in one study,[16] 13 (35 percent) of 37 tients reported no symptoms during the electrocard graphic changes. In another study,[17] 309 (75 perce of 411 episodes of transmural ischemia were not companied by angina. In that study, nitroglycerin ministered hourly significantly reduced the freque of these episodes, thus supporting the concept that th electrocardiographic abnormalities represented painl myocardial ischemia.

Ventricular ectopic activity can also be obser without angina. When the ventricular premat complexes are frequent or of a malignant nature (c

* Although not symptomatic during this test, almost all patients in these studies had a history of angina or prior myocardial infarction (text).

CAD = coronary artery disease.

plets, ventricular tachycardia) and coronary artery disease is present, one can presume that the ectopic activity is related to myocardial ischemia, especially because many of the arrhythmic episodes are also associated with S-T segment changes in normally conducted complexes. One of the better documented studies[18] of angina and ectopic activity demonstrated that frequent ventricular complexes, couplets or ventricular tachycardia was present in 27 (23 percent) of 115 patients with coronary disease whose maximal exercise tests were stopped because of fatigue rather than angina. This figure was three times higher than that observed in the group with angina—an observation that will be commented on further when the clinical significance of this syndrome is discussed.

Prevalence of Silent Myocardial Ischemia in Asymptomatic Patients

In addition to patients with coronary disease who have angina with some, but not all, episodes of myocardial ischemia, some patients apparently never have symptoms. How common are they? The most extensive study in this field was performed by Erikssen et al.[19] in Norway. Using a combination of screening techniques, the most important of which was the exercise test, they studied more than 2,000 presumably healthy and asymptomatic men aged 40 to 59 years. Of this group, 105 men were subsequently referred for coronary arteriography on the basis of the screening procedures, and 67 had evidence of hemodynamically significant coronary artery disease, including 51 with multivessel disease. Thus, approximately 3.5 percent of this total group had truly asymptomatic and significant coronary artery disease. Confirmation of this estimate will be difficult because normally few patients of this type are referred for angiographic study in most clinical centers. Froelicher et al.[20] used a similar approach in 1,390 asymptomatic U.S. Air Force crewmen, mostly between the ages of 35 and 55 years. One hundred thirty-eight were selected for coronary arteriography. Thirty-three (2.2 percent) of the 1,390 crewmen had significant coronary artery disease, including 18 with multivessel disease.

On the basis of these two studies, it would appear that 2 to 4 percent of middle-aged men have asymptomatic significant coronary artery disease. That this figure is realistic can also be deduced from epidemiologic studies. For example, Bruce et al.[21] estimated that 3.5 percent of an asymptomatic male population had a seven-fold risk of any subsequent coronary heart disease event (angina, myocardial infarction or sudden death) on the basis of abnormal exercise test results. Presumably, this subgroup would have been found to have coronary artery disease if subjected to coronary arteriography. Further evidence that this estimate is accurate can be obtained by reviewing autopsy studies performed in men *not* known to have coronary artery disease before death and whose death was due to trauma or other causes apparently unrelated to heart disease. In summarizing such data, Diamond and Forrester[22] found a 6.4 percent prevalence rate of coronary artery disease. This figure is not that dissimilar to the others cited when one realizes that the autopsy findings do not necessarily imply that all the lesions caused active ischemia during life.

Clinical Significance in Symptomatic Individuals

The relative frequency of silent myocardial ischemia (as noted in the studies cited) suggests that many patients with otherwise symptomatic coronary artery disease will have one or more episodes of myocardial ischemia without anginal symptoms. How often a given patient will have repeated asymptomatic episodes is unclear from the published data. The ambulatory electrocardiographic studies of Schang and Pepine[17] suggest that such episodes are frequent events in symptomatic patients. Whether the severity of coronary artery disease influences the occurrence of these episodes is also unclear. One exercise electrocardiographic study[13] revealed no distinguishing features between patients with and without test induced angina, whereas two others[11,14] showed a lesser prevalence of multivessel disease in the asymptomatic group.

Do episodes of silent myocardial ischemia involve less myocardium than angina-related episodes, so that the prognosis of patients who commonly experience silent ischemia is different from that of patients with fewer such episodes? There are no data available to answer this question directly, but there is some pertinent information regarding patients with prior infarction who are now asymptomatic but have an abnormal exercise test. Many of these patients—as many as 75 percent in one study[23]—have ischemic S-T changes without test-induced angina. Most importantly, short-term survival appears to be related to the development of the S-T segment changes, independent of their association with test-induced angina.[24]

At present, patients who have episodes of both symptomatic and asymptomatic ischemia are treated with a full range of medical and surgical measures. Patients who are asymptomatic after myocardial infarction present a more difficult problem. In those with a positive exercise test, a case can be made for "prophylactic" therapy with propranolol, especially in light of the results of European studies suggesting a protective effect of beta adrenergic blockade in patients with prior infarcts. The role of surgery is unclear (see later).

Clinical Significance in Asymptomatic Patients

Even before publication of the reports of Erikssen et al.[19] and Froelicher et al.,[20] epidemiologic studies of sudden unexpected death and clinical and postmortem studies of silent myocardial infarction indicated to physicians that many patients with extensive coronary arterial obstruction do not have angina pectoris in any of its recognized forms. In such patients, ischemic attacks presumably go unnoticed until a fatal event ensues or evidence of a prior silent infarction is detected in a routine electrocardiogram. How can such persons be identified? What is their prognosis? Should they be treated, and how?

Identification: Identification of asymptomatic or only vaguely symptomatic persons with severe coronary

artery disease must by nature be fortuitous in the absence of large-scale screening protocols such as those cited.[19,20] Some of these persons are suspected of having coronary artery disease before a fatal or morbid event occurs because casual electrocardiograms have shown arrhythmias or ST-T wave abnormalities. More commonly, they are identified because cardiac catheterization is performed as the result of a markedly positive exercise test, often (but not always) in the setting of multiple coronary risk factors.[25] Should all presumably healthy middle-aged men undergo exercise testing to detect those with a defective anginal warning system? At present, exercise testing of asymptomatic persons is an accepted procedure only in persons in whom latent coronary disease could endanger public safety (such as airline pilots) or those who are about to engage in stressful exercise programs or have a strong family history of premature coronary artery disease. There are important objections to mass screening. First, the application of Bayes' theorem has emphasized the limitations of conventional criteria for identifying the true-positive response to exercise tests in asymptomatic groups.[22] More stringent criteria (involving depth of S-T depression and its time of onset and duration, as well as associated blood pressure and heart rate response) could be used to screen out the false-positive responses in patients without coronary artery disease, but these would obviously reduce the sensitivity of the test.

However, even with more stringent exercise criteria it has been argued that an S-T response without pain suggests a limited amount of ischemic myocardium. In such cases, other noninvasive tests such as myocardial perfusion scintigraphy during exercise with thallium-201 or related isotopes might play a role. Myocardial scintigraphy has been used with good results in asymptomatic patients with a positive exercise test to separate true-positive from false-positive responses.[26,27] Alternatively, an exercise radionuclide ventriculogram or exercise echocardiogram could be obtained. Because the latter procedure usually allows good visualization of the interventricular septum, it would seem particularly well suited to detection of silent ischemia due to stenosis of the left anterior descending coronary artery (as manifested by decreased septal thickening and wall motion) when the exercise electrocardiogram demonstrates S-T depression in the anterior precordial leads. Fluoroscopic examination to detect coronary arterial calcification has been advocated, because a positive result also improves the reliability of the exercise test.[22] All of these additional procedures increase the cost of the detection process, which leads to the second objection. The low incidence rates of coronary artery disease in this group of patients (apparently 5 percent or less from the studies previously cited) makes the cost-benefit ratio for detecting such persons economically unfeasible, especially because no consensus exists on the course of action once such persons have been identified.

Prognosis: Although prognosis in this group is not known, can one assume that it is in these patients that many of the sudden deaths will be recorded? This is not an unreasonable premise when one recalls the arrhythmia study of Jelinek and Lown[18] cited earlier. Because the occurrence of ventricular ectopic activity was much greater in patients without test-induced angina, these authors noted that "the occurrence of test-induced angina seemed to protect the patient from more work and the occurrence of arrhythmias."

Despite the implication that silent ischemia may present more of a risk than asymptomatic ischemia, there is no evidence to support this contention. In fact, the available evidence is to the contrary. For example, in a study performed at the National Institutes of Health,[28] the mortality rate of a group of patients (mostly with multivessel disease) who were either completely asymptomatic (18 percent) or mildly (82 percent) asymptomatic was only 2 percent a year. In contrast, one would expect a 6 to 7 percent mortality rate in symptomatic patients with a similar extent of vessel disease and left ventricular asynergy.[29] Furthermore, the presence of chest pain during a positive exercise test has been reported[30] to be a more ominous prognostic omen than its absence. This finding implies that the outlook is more favorable for patients who are free of angina during ischemia than for those who experience symptoms.

Treatment: Because the natural history of totally asymptomatic patients is unknown—and there are suggestions that it may be better than that of symptomatic patients—no definitive arguments can be made for the institution of either medical or surgical therapy. For patients whose disease is discovered only fortuitously through exercise testing and coronary arteriography, there are strenous objections to surgery except, perhaps, in patients with left main coronary lesions or other special conditions.[28,31] Although surgery has been convincingly demonstrated to prolong life only in randomized trials of *symptomatic* patients with left main[32] and triple vessel coronary artery disease,[33] two recent studies[34,35] have shown excellent results with surgery in asymptomatic subjects. These patients, most of whom had a prior myocardial infarction, had no perioperative mortality, a high rate of regression of abnormal exercise tests and excellent 3 to 5 year survival, but there are no medical data with which to compare these results.

Conclusions

Why some patients with coronary artery disease have episodes of silent myocardial ischemia is not well understood, but because the generation of the myocardial pain impulse is a complex phenomenon, it should not be surprising to find persons whose subjective symptoms are either not present or too vague to be clearly defined by the patient or his physician. In addition to differences in threshold of central pain sensitivity and in awareness factors in the peripheral organ system, there are the factors of psychologic denial and the influence of cultural and subcultural norms concerning the acceptability of symptoms in otherwise healthy people. Thus, with metabolic, humoral, neurologic, psychologic and sociologic factors all involved in the

sensation of angina, the variability in the awareness and description of this symptom is not unexpected.[36] Studies in patients receiving a cardiac transplant have demonstrated that cardiac denervation can result in silent myocardial ischemia, and it may be that in some patients with a defective anginal warning system, the nerve endings have been damaged or destroyed as a result of a prior myocardial infarction. It has also been speculated that diabetic patients have a greater frequency of this syndrome, presumably because of denervation of autonomic nerves. However, there remains a large group of persons who are not diabetic and have not had a prior myocardial infarction but respond to myocardial ischemia with a defective anginal warning system. It remains to be determined whether such persons have some unidentified primary alteration in their threshold to pain in general.

The prevalence of the disorder is not known, but on the basis of studies using exercise electrocardiography, ventriculography and myocardial perfusion scintigraphy, it would appear to be relatively common for patients with a history of anginal symptoms to have episodes of silent myocardial ischemia. The prevalence rate of truly asymptomatic patients appears to be less than 5 percent. The prognosis of symptomatic patients with episodes of silent ischemia is probably similar to that of patients with symptomatic ischemia, but that of truly asymptomatic patients is not known. The available preliminary data suggest that the prognosis in the group may be better (or at least no worse) than that of patients with anginal symptoms. The decision to institute medical or surgical therapy obviously depends on this type of prognostic data. The choice of surgical therapy is a particularly controversial one, because there is not yet a consensus as to the role of surgery in symptomatic patients.[37] It would appear, therefore, that large-scale prognostic surveys of patients with silent myocardial ischemia are needed. Until the results of such studies are available, many questions about this challenging syndrome will remain unanswered.

IN APPRECIATION

The Journal thanks the following persons who, although not members of the Editorial Board, gave their time in 1979 to the review of submitted manuscripts.

Ronald Abel, Newark, New Jersey
J. A. Abildskov, Salt Lake City, Utah
Crawford W. Adams, Nashville, Tennessee
Forrest H. Adams, Los Angeles, California
Robert Adolph, Cincinnati, Ohio
John Ambrose, New York, New York
Gary J. Anderson, Philadelphia, Pennsylvania
Evangelos Angelakos, Philadelphia, Pennsylvania
Rene A. Arcilla, Chicago, Illinois
Wilbert S. Aronow, Long Beach, California
Stephen M. Ayres, Saint Louis, Missouri
Marvin B. Bacaner, Minneapolis, Minnesota
Mortimer Bader, New York, New York
Richard Bader, New York, New York
Alan Bahler, Livingston, New Jersey
Vidya S. Banka, Philadelphia, Pennsylvania
Serge S. Barold, Rochester, New York
Murray Baron, New Hyde Park, New York
Talit Bashour, Washington, DC
Lewis Becker, Baltimore, Maryland
Benjamin Befeler, Hialeah, Florida
Alberto Benchimol, Phoenix, Arizona
Jonas Beregovich, New York, New York
Daniel S. Berman, Los Angeles, California
Charles A. Bertrand, White Plains, New York
Saroja Bharati, Chicago, Illinois

For 30 years you've known us as

Now, we are

. . . and here's what this means to you:

- A comprehensive product line that includes patient monitoring equipment, advanced echocardiographs, MEDDARS cath lab recorders and other fine medical products, all under the E for M/Honeywell name.
- Accelerated research and development, enriched by Honeywell technology, for the ongoing creation of new products to meet your ever-evolving needs.
- Expanding capabilities and greater resources than ever before!

But some things stay the same . . .

We'll continue with the full E for M product line you have grown to rely on. Our free 2-year warranty (for former E for M products) stays as solid as ever, according to the terms and conditions thereof. And, our *really* personal sales and service philosophy remains unchanged.

In most ways, then, we're still the same company. We've always done our best, worked our hardest to please you. But we will have to double our efforts. Because now, we have 2 great names to live up to!

Together, we'll show you a better way

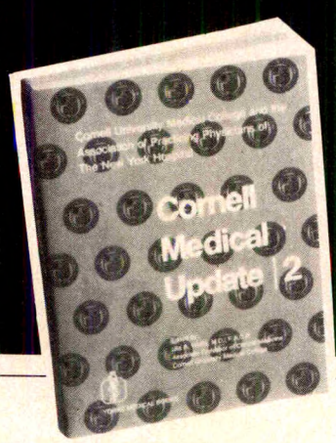
Now in book form...the latest **Update Your Medicine** lectures

Helps you keep up with the new advances in your speciality in the comfort of your home or office.



CORNELL MEDICAL UPDATE/2

Edited by LILA A. WALLIS, MD, FACP

Just published with all new material—specialties expanded.

The series CORNELL MEDICAL UPDATE breaks all medical book tradition with its workbook format that gives practicing physicians a quick overview of the latest advances in their speciality. It transcribes into book form the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice.

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Each of the 23 lectures is presented in a workbook format for easy reading and quick comprehension.

1. Cardiology, I: Applications of Anticoagulation; Coronary Artery Bypass Surgery; Valvular Heart Disease
2. Cardiology, II: Congenital Heart Disease in Adults, Part I
3. Cardiology, III: Congenital Heart Disease in Adults, Part II
4. Hematology: Hemostasis Made Easy
5. Gastroenterology, I: Cricoesophageal Achalasia and Gastroesophageal Reflux
6. Gastroenterology, II: Pharmacology of Acid Peptic Disease Therapy
7. Genetics, I: Basic Genetics
8. Genetics, II: Chromosomal Abnormalities
9. Genetics, III: Clinical Genetics
10. Gynecology, I: New Diagnostic Procedures and Therapy
11. Gynecology, II: New Diagnostic Procedures
12. Obstetrics: Prenatal Diagnosis of Genetic Diseases and Abnormalities
13. Infectious Diseases, I: Antimicrobial Therapy
14. Infectious Diseases, II: Virology
15. Nephrology, I: Renal Glomerular Disease
16. Nephrology: II: Management of Chronic Renal Failure
17. Ophthalmology, I: Progress in Ophthamology
18. Ophthalmology, II: Diabetic Retinopathy Vitrectomy Study
19. Psychopharmacology, I: Antipyschotic Drugs and Minor Tranquilizers
20. Psychopharmacology, II: Antidepressant Drugs
21. Pulmonary Medicine: Recent Advances
22. Rheumatology: Recent Advances
23. Calcium Metabolism: Disorders of Calcium Metabolism

THE ECG OF THE 80's...

It Sets The Standard For Years To Come

The Standard For Cost Efficiency Total time from patient set-up through record mounting can be reduced by half, enabling labor cost savings in the competitively priced VS-550. The savings are due to the total system concept of the instrument...from automatic lead switching to the unique PERFform™ perforated paper and mounting system.

The Standard For Reliability New technology and over 60 years of experience...the VS-550 combines the best of both to give you high performance and reliability. The unit features a rugged high impact molded case, microprocessor-controlled circuitry, and a touch control panel that far surpasses in reliability, the standard mechanical lead selector switch.

The Standard For Operating Ease Simplicity of operation is achieved in the VS-550, from its instant paper loading through its automatic lead and calibration marking. And, at just the touch of a switch...an optional AC Eliminator removes line power interference without distorting the ECG.

The Standard For Serviceability The VS-550 has been designed for simplicity of service and has the ability to instantly analyze instrument performance, on demand, through the AUTOTEST™ program. Most service adjustments can be made without disassembly. Downtime is reduced to a minimum, because of plug-in modular construction and the backup you get from our nationwide service organization.

For demonstration or ordering information, please write or call collect: 73 Spring St., Ossining, N.Y. 10562, Tel: (914) 941-8100, Ext. 550.

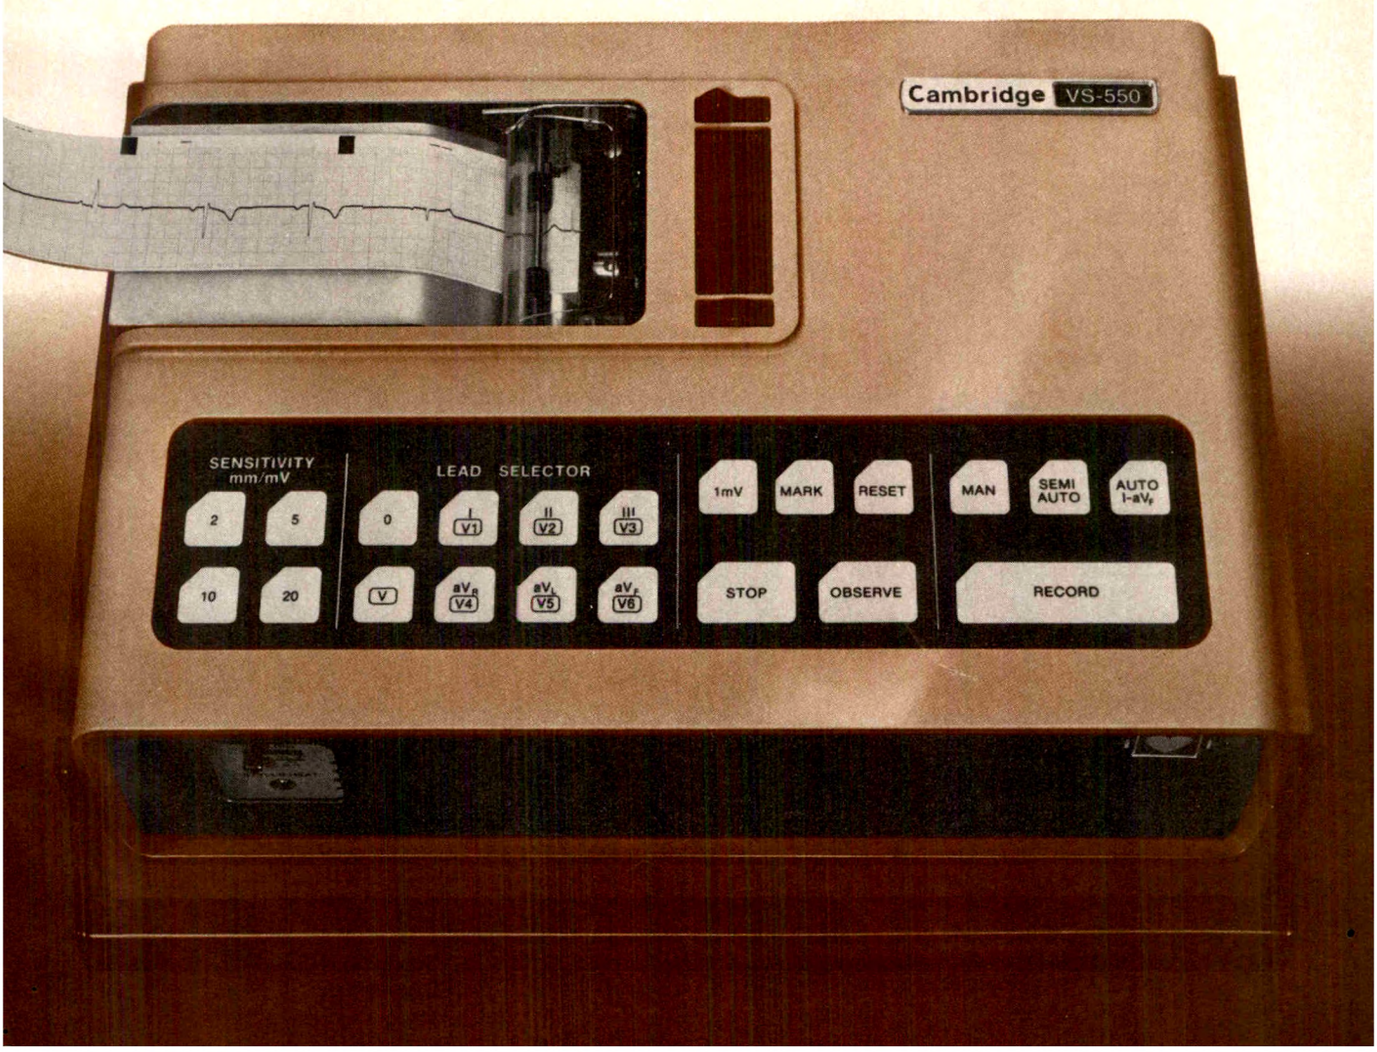
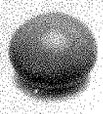
The VS-550: The New Standard In Single Channel Electrocardiography... From The Company Who Developed The First



The potassium masquerade is over



Potassium with nothing to hide

There's no longer any need to try to hide the taste of potassium chloride—because KAON-CL TABS have no taste.
Thus your patients who can't or won't take liquid supplements have an acceptable alternative that enables them to get the potassium they need.

Wax-matrix tablets minimize likelihood of GI complications.
The special wax matrix used in KAON-CL TABS permits gradual release of potassium chloride in the GI tract. Because the potassium is slowly released, the possibility of high localized GI concentrations is limited. The reported frequency of GI lesions with wax-matrix tablets is less than one per 100,000 patient-years. There have been only two equivocal cases of GI bleeding reported with KAON-CL TABS to date and no reports of small bowel stenosis or ulceration. However, clinical experience is insufficient at this time to indicate that the incidence is other than the stated numerical ratio.

Logical, easily adjustable dosage. One tablet t.i.d. provides 20 mEq of potassium, the amount generally considered necessary for prevention of hypokalemia. Two tablets t.i.d. provide 40 mEq of potassium, usually adequate for the treatment of mild potassium depletion. Dosage should be adjusted to individual patient needs. In cases of more severe potassium depletion, 100 mEq daily or more may be required.

Patients stay on

KAON-CL TABS®
(potassium chloride) Controlled Release Tablets

For summary of prescribing information, please see following page.

WARREN-TEED LABORATORIES
DIVISION OF **ADRIA LABORATORIES INC.**
COLUMBUS, OHIO 43215

KAON-Cl TABS® (potassium chloride) Controlled Release Tablets

Description: Kaon-Cl Tabs is a sugar coated (not enteric-coated) tablet containing 500 mg potassium chloride (equivalent to 6.7 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: *Hyperkalemia*—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon-Cl Tabs (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient years. Kaon-Cl Tabs should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Bottles of 100, 250 and 1000.

NEW BOOKS

Echocardiology

edited by
CHARLES T. LANCEE
Thorax Center, Erasmus University, Rotterdam, The Netherlands

DEVELOPMENTS IN CARDIOVASCULAR MEDICINE, 1

1979, xx, 489 pp.
Cloth Dfl. 140.00/US $ 73.70
ISBN 90-247-2209-8

This book contains over 60 papers prepared for the 3rd Symposium on Echcardiology held in Rotterdam, June 1979. The first part of the book is devoted to echocardiology in adults with contributions on general applications, ischemic disease, left ventricular function analysis and cardiac valve disease. The second part is devoted to pediatric echocardiology, while the last part contains a wide variety of contributions on instrumentation and technology. The topics covered yield an almost complete review of echocardiographic techniques with among its contributors some of the world's most distinguished specialists.

Cardiac Dynamics

edited by
JAN BAAN and ALEXANDER C. ARNTZENIUS
Leiden University Hospital, The Netherlands
EDWARD L. YELLIN
Albert Einstein College of Medicine, Bronx, NY, USA

DEVELOPMENTS IN CARDIOVASCULAR MEDICINE, 2

1979, x, 545 pp.
Cloth Dfl. 155.00/US $ 81.60
ISBN 90-247-2212-8

A selection of papers presented at the Third International Conference on Cardiovascular System Dynamics held at the University of Leiden in August 1978, is published in this book. The chapters have been grouped together around the following topics: cardiac muscle mechanics, cardiac chamber dynamics, pump function and filling, pump function and ejection, assessment of cardiac performance, and energy losses across valves. The topics are treated from a standpoint of basic research as well as from a clinical viewpoint.

Fundamentals of Cardiac Pacing

edited by
HILBERT J. TH. THALEN
Groningen University Hospital, The Netherlands
CLAUDE C. MEERE
Montreal Heart Institute, Canada

DEVELOPMENTS IN CARDIOVASCULAR MEDICINE, 3

1979, x, 255 pp.
Cloth Dfl. 75.00/US $ 39.45
ISNB 90-247-2245-4

The VIth World Symposium on Cardiac Pacing in Montreal 1979 opened with a course meant to be an introduction for newcomers and an updating refresher course. It also provided a link between the various fields of knowledge involved in cardiac pacing needed by experienced persons. Invited guest lecturers were selected for their world recognized expertise in the individual subjects. This book is a collection of the various presentations on historical, clinical, electrophysiological and technical aspects of cardiac pacing.

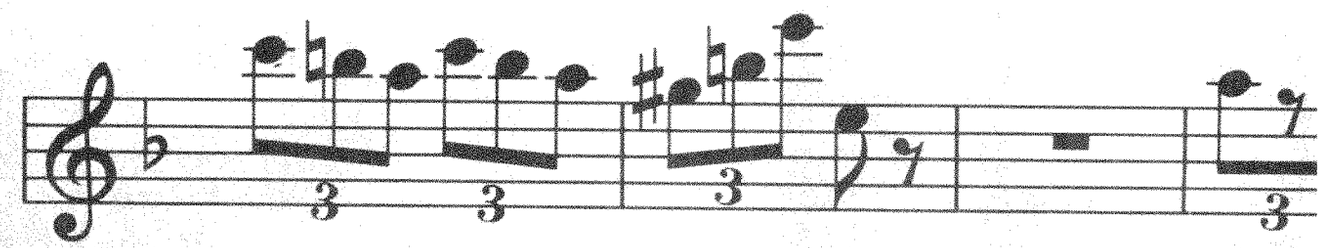
CARDIOLOGY: FRESNO, CALIFORNIA

The University of California, San Francisco is searching for a chief of cardiology in the Fresno-Central San Joaquin Valley Medical Education Program. The position is situated at the Veterans Administration Medical Center in Fresno. Candidate should be qualified for academic appointment at the level of associate professor or professor. Interested individuals may submit their C.V. to Howard F. Morrelli, M.D., Professor of Medicine and Pharmacology, Chief, Medical Service, Veterans Administration Medical Center, 2615 E. Clinton, Fresno, CA 93703. The University of California is an equal opportunity employer.

An impressive therapeutic performance...



In tune with contemporary antihypertensive thinking

Today antihypertensive therapy has gone beyond the empirical addition of one drug to another. Today's clinician looks for agents that coordinate their action for smoother, more effective control.

A prime example is increasing use of the Apresoline/beta-blocker/diuretic regimen in moderate-to-severe hypertension. Beta blockers, though effective and generally well tolerated, do not lower the high peripheral resistance found in virtually all long-standing hypertension. As a vasodilator, Apresoline deals directly with the problem. It can decrease total peripheral resistance by more than 60%.

Beta blockers, on the other hand, specifically reduce cardiac output, which tends to rise through reflex action with Apresoline therapy, while diuretics counteract the retention of sodium and extracellular fluid.

Harmonizing with the antihypertensive life-style

The Apresoline/beta-blocker/diuretic regimen is relatively free of serious side-effect problems that interfere with daily living.

As the only therapeutic action of Apresoline is its direct arteriolar vasodilator effect, it avoids many distressing side effects. Sexual dysfunction, drowsiness, lethargy, and sedation are virtually unknown. Postural hypotension is rare. These side effects are usually also avoided with a beta blocker.

Accompanying a fall in blood pressure from Apresoline is an increase in cardiac rate and output. Apresoline also maintains or increases renal and cerebral blood flow. As with any antihypertensive agent, use with caution in patients with advanced renal damage. Contraindicated in coronary artery disease.

After a diuretic...

Apresoline® & (hydralazine)

the beta blockers

Please turn page for brief prescribing information.

CIBA

Apresoline® hydrochloride
(hydralazine hydrochloride USP)

TABLETS

INDICATIONS

Essential hypertension, alone or as an adjunct.

CONTRAINDICATIONS

Hypersensitivity to hydralazine; coronary artery disease; and mitral valvular rheumatic heart disease.

WARNINGS

Hydralazine may produce in a few patients a clinical picture simulating systemic lupus erythematosus. In such patients hydralazine should be discontinued unless the benefit-to-risk determination requires continued antihypertensive therapy with this drug. Symptoms and signs usually regress when the drug is discontinued but residua have been detected many years later. Long-term treatment with steroids may be necessary.

Complete blood counts, L.E. cell preparations, and antinuclear antibody titer determinations are indicated before and periodically during prolonged therapy with hydralazine even though the patient is asymptomatic. These studies are also indicated if the patient develops arthralgia, fever, chest pain, continued malaise or other unexplained signs or symptoms.

A positive antinuclear antibody titer and/or positive L.E. cell reaction requires that the physician carefully weigh the implications of the test results against the benefits to be derived from antihypertensive therapy with hydralazine.

Use MAO inhibitors with caution in patients receiving hydralazine.

When other potent parenteral antihypertensive drugs, such as diazoxide, are used in combination with hydralazine, patients should be continuously observed for several hours for any excessive fall in blood pressure. Profound hypotensive episodes may occur when diazoxide injection and Apresoline (hydralazine hydrochloride) are used concomitantly.

Usage in Pregnancy

Animal studies indicate that hydralazine is teratogenic in mice, possibly in rabbits, and not in rats. Teratogenic effects observed were cleft palate and malformations of facial and cranial bones. Although clinical experience does not include any positive evidence of adverse effects on the human fetus, hydralazine should not be used during pregnancy unless the expected benefit clearly justifies the potential risk to the fetus.

PRECAUTIONS

Myocardial stimulation produced by Apresoline can cause anginal attacks and ECG changes of myocardial ischemia. The drug has been implicated in the production of myocardial infarction. It must, therefore, be used with caution in patients with suspected coronary artery disease.

The "hyperdynamic" circulation caused by Apresoline may accentuate specific cardiovascular inadequacies. An example is that Apresoline may increase pulmonary artery pressure in patients with mitral valvular disease. The drug may reduce the pressor responses to epinephrine. Postural hypotension may result from Apresoline, but is less common than with ganglionic blocking agents. Use with caution in patients with cerebral vascular accidents.

In hypertensive patients with normal kidneys who are treated with Apresoline, there is evidence of increased renal blood flow and a maintenance of glomerular filtration rate. In some instances improved renal function has been noted where control values were below normal prior to Apresoline administration. However, as with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage.

Peripheral neuritis, evidenced by paresthesias, numbness, and tingling, has been observed. Published evidence suggests an antipyridoxine effect and the addition of pyridoxine to the regimen if symptoms develop.

Blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura, have been reported. If such abnormalities develop, discontinue therapy. Periodic blood counts are advised during prolonged therapy.

The Apresoline tablets (10 and 100 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Adverse reactions with Apresoline are usually reversible when dosage is reduced. However, in some cases it may be necessary to discontinue the drug.

Common: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; tachycardia; angina pectoris.

Less frequent: Nasal congestion; flushing; lacrimation; conjunctivitis; peripheral neuritis, evidenced by paresthesias, numbness, and tingling; edema; dizziness; tremors; muscle cramps; psychotic reactions characterized by depression, disorientation, or anxiety; hypersensitivity (including rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, and, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; paralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura; hypotension; paradoxical pressor response.

DOSAGE AND ADMINISTRATION

Initiate therapy in gradually increasing dosages; adjust according to individual response. Start with 10 mg 4 times daily for the first 2 to 4 days, increase to 25 mg 4 times daily for balance of first week. For second and subsequent weeks, increase dosage to 50 mg 4 times daily. For maintenance, adjust dosage to lowest effective levels.

The incidence of toxic reactions, particularly the L.E. cell syndrome, is high in the group of patients receiving large doses of Apresoline.

In a few resistant patients, up to 300 mg Apresoline daily may be required for a significant antihypertensive effect. In such cases, a lower dosage of Apresoline combined with a thiazide, reserpine, or both may be considered. However, when combining therapy, individual titration is essential to insure the lowest possible therapeutic dose of each drug.

a "clean break" from the past in angina pectoris*

One press of a finger solves two problems

1. for the physician: precise dosage titration
2. for the patient: easier compliance with your dosage adjustments

ISORDIL® TITRADOSE®

(ISOSORBIDE DINITRATE) (E.Z. SPLIT®†) Oral Tablets: 5 mg, 10 mg, 20 mg, and 30 mg

Because recent studies demonstrate that higher dosages are often indicated

now 30 mg ISORDIL® TITRADOSE®

(ISOSORBIDE DINITRATE) Oral Tablets

*Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

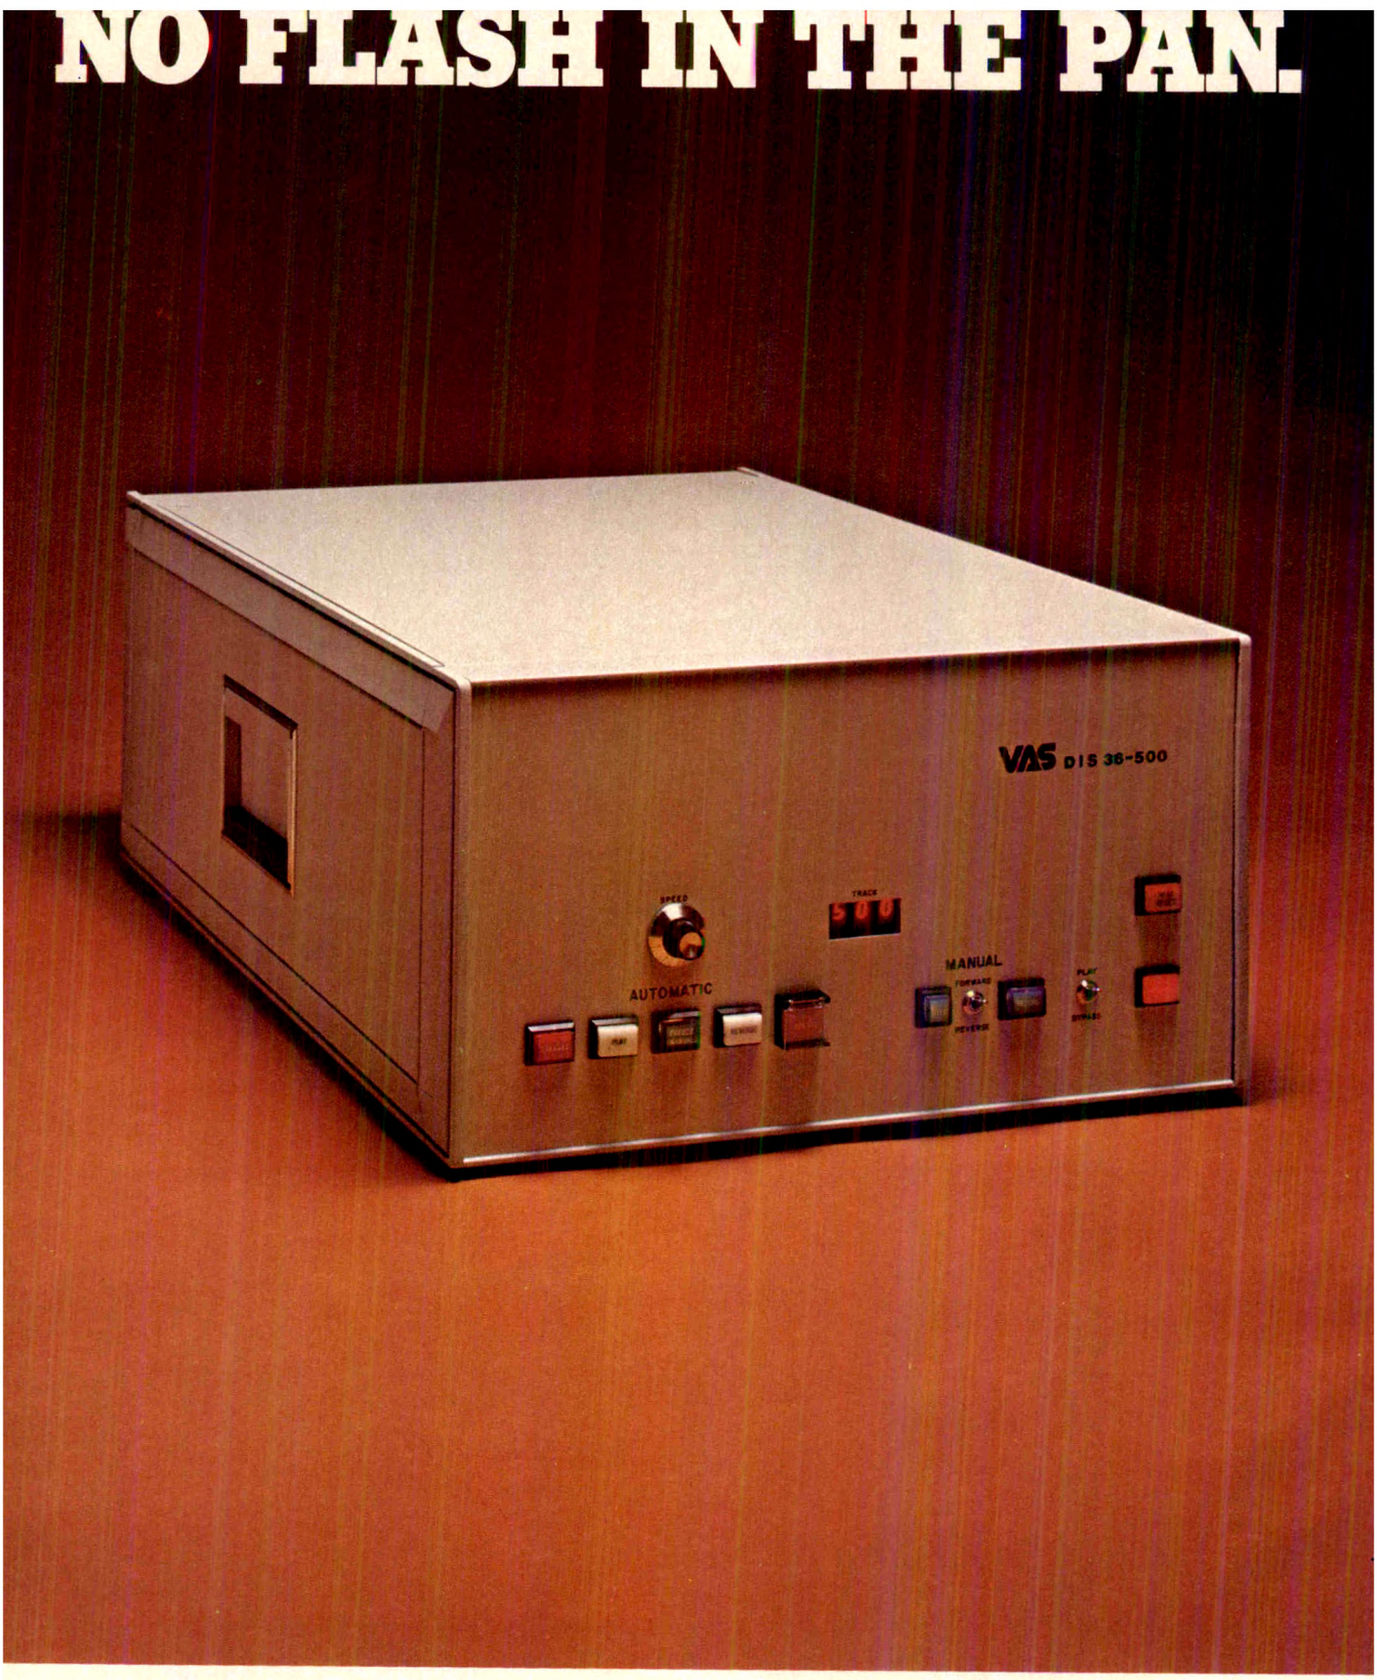
NO FLASH IN THE PAN.



BIOFEEDBACK BIOFEEDBA

The VAS Dynamic Image Store® (DIS) Video Disc Recording System records each sequential flashing image during a spot filming series and then replays that image until the next exposure is made. It's like viewing continuous flouroscopy —without the continuous radiation. So now you can follow the progression of the contrast bolus while panning—without the flashing—without waiting for the film to be developed before you determine the next injection.

Optimally, the DIS reduces radiation dosage by lowering exposure time and letting you replay any sequence over and over again with no image degradation. Instantly and flicker free. It achieves this with Cine Lock, which records the cine run on the disc for instant replay in variable slow motion (6-60 images per second), real-time, or frame freeze that lets you advance the image frame by frame for an analysis of the injection; Photo Spot, which fills in between the flash and plays back the film; and Pulsed Flouroscopy for dose reduction during catheter manipulation.

Ask your system's manufacturer or local sales representative about us. In addition to angiographic and heart catheterization applications, we have a full line of Video Disc Recording Systems that provide instant image replay in Ultrasound and Mobile C-arm, as well as dose reduction in x-ray applications. Then call us at (213) 320-8334. Or write VAS Corporation, 2525 Maricopa Street, Torrance, California 90503. We'll show you how our DIS Video Disc Recording System not only reduces your chances of missing what you wanted on film, but also reduces your patient's radiation dosage.

TORSADE DE POINTES AND MITRAL VALVE PROLAPSE

Kossmann's recent editorial, "Torsade de pointes,"[1] is a timely discussion of an interesting and clinically relevant variant of ventricular tachycardia. Kossmann believes that, despite the absence of a well documented example, mitral valve prolapse should be added to the list of "causes" because the ventricular tachycardia seen with it is often refractory to "conventional" treatment. In support of his thesis is the following example of torsade de pointes in a young black woman with mitral valve prolapse.

Case report: At age 10, this young woman began to experience fainting spells which gradually increased in frequency until February 1970, when at age 15 she experienced 25 to 30 episodes during a 12 to 18 hour period. She was having paroxysmal ventricular tachycardia and fibrillation (Fig. 1) that was not suppressed by quinidine and actually worsened with its use. Lidocaine was ineffective even though enough was given to cause seizures. Finally, overdrive ventricular pacing controlled the arrhythmia and orally administered propranolol (160 mg/day) prevented further disturbance. No cause for the arrhythmia was found although the Q-Tc interval (0.43) was prolonged. Subsequently, an apical systolic click was heard (Fig 1) and mitral valve prolapse was documented by echocardiography.

Comment: The common thread of the several "causes" of torsade de pointes is an underlying nonuniform electric recovery of ventricular tissue that is reflected in a long Q-T interval and failure to respond to usual antiarrhythmic agents (quinidine, procainamide), which are not only ineffective but may worsen the situation. Although the exact mechanism or mechanisms of sudden death in mitral valve prolapse are still at issue, it is clear that many patients, including those who are asymptomatic, have a long Q-T interval[2]; therefore it seems wise to avoid any therapy that will prolong repolarization and thereby promote nonuniform recovery of ventricular tissue.

Kenneth R. Bennett, MD, FACC
Jackson, Mississippi

REPLY

Prophets have little place in medical science. The temptation to predict torsade de pointes as the kind of refractory tachycardia that might be encountered in the syndrome associated with prolapse of the mitral valve clearly overwhelmed this ordinarily cautious author. I am everlastingly grateful to

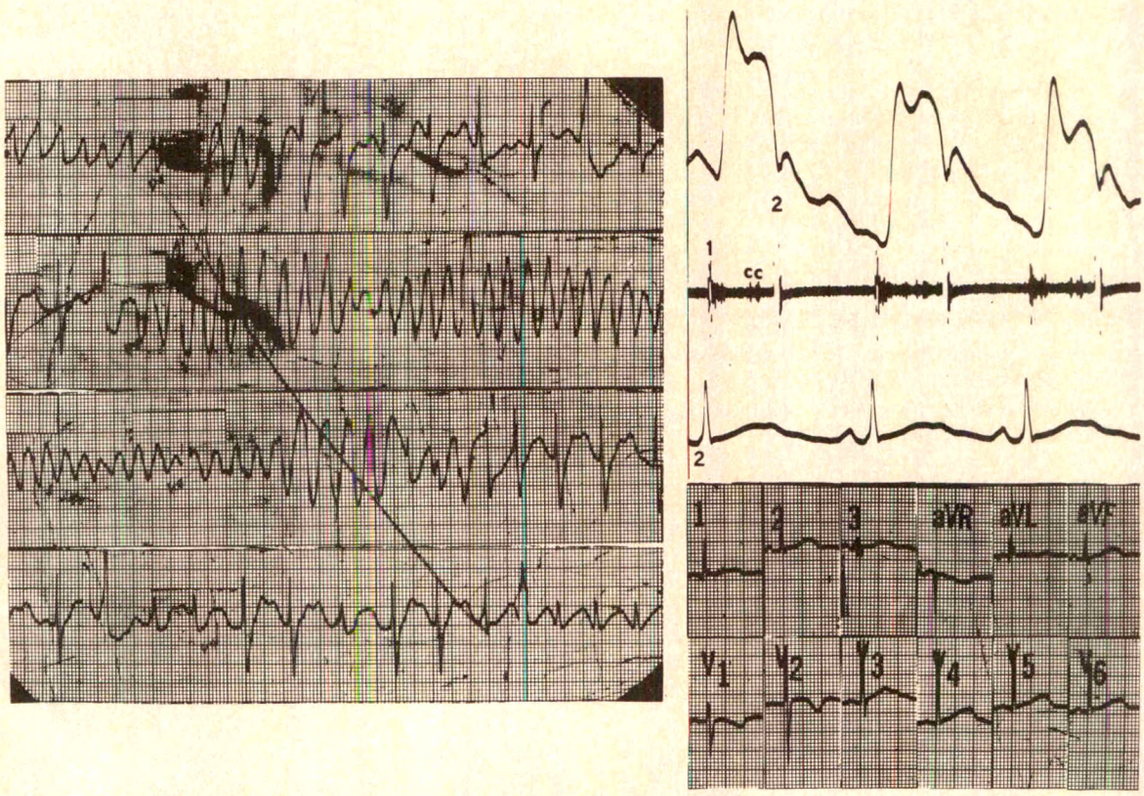

FIGURE 1. Top left, February 1970. Bizarre, undulating ventricular tachycardia characteristic of torsade de pointes. Strips are a continuous record of lead V_4. **Top right,** May 1974. Carotid pulse tracing with apical phonocardiogram demonstrating late systolic click(s). A prominent U wave is seen in electrocardiographic lead II. **Bottom right,** 12 lead electrocardiogram recorded while the patient was taking propranolol (160 mg/day). The Q-Tc interval (0.40) is at the upper limits of normal.

Bennett for rescuing me from categorization as a false prophet by providing the first incontrovertible evidence to support the prediction made. Bennett's successful management of his case with propranolol should be noted by all who treat arrhythmias.

TREATMENT OF TORSADE DE POINTES

Two recent articles[1,2] in this Journal discuss torsade de pointes arrhythmias. In 1977, we described the occurrence of "torsade de pointes" arrhythmias in 8 patients selected from 1,100 patients treated in our coronary care unit.[3] We proposed to call the arrhythmia "ventricular fibrillo-flutter" in analogy with its atrial counterpart. For this selection we used the criteria described by Desertenne et al.[4] Two patients died of the rhythm disturbance and the others were able to leave the hospital in good condition. They all showed a typical pattern of "torsade de pointes" episodes and all but one had greatly prolonged Q-T_C intervals (0.60 s or more) during sinus rhythm.

The origin of this arrhythmia was attributed to severe coronary ischemia in three patients, acute myocardial infarction combined with digitalis intoxication in one patient, hypokalemia in two others, thioridazine treatment (300 mg/day) in one and subarachnoid hemorrhage in the eighth patient. All patients were treated with electric defibrillation during episodes of "torsade de pointes" and subsequently with lignocaine and aprindine infusions to prevent recurrences. One patient required electric pacing for severe sinus bradycardia.

It is our impression, contrary to the view of the French authors,[5,6] that the particular form of arrhythmia can be prevented by the administration of these two drugs providing that the basic rhythm is not too slow. Otherwise, electric pacing at a rate of about 100 to 110 beats/min seems to be a good preventive measure.

The appearance of severe ventricular arrhythmias due to disopyramide toxicity seems to be a very rare complication. We use disopyramide therapy for ventricular arrhythmias as a second choice drug after failure with lignocaine. To date we have not observed ventricular arrhythmias due to disopyramide toxicity. However, we have never used the large dosage regimens (1,200 to 2,400 mg/day) mentioned in Dr. Meltzer's article; our standard dosage is 600 mg/day.

In conclusion, we make a plea for consideration of the "torsade de pointes" phenomenon as a distinct electrocardiographic and clinical entity for etiologic, morphologic and therapeutic reasons.

REPLY

Although multiple nondrug-related conditions have been associated with atypical ventricular tachycardia, drug toxicity is a frequent cause. Because quinidine is perhaps the most prominent offender, and disopyramide has similar electrophysiologic effects, we were not surprised to note a slow "torsade de pointes" phenomenon with the disopyramide toxicity in our patient. As stated in our article, the overdose was inadvertent, probably a consequence of lack of familiarity with a newly introduced drug by the house staff and nurses. Indeed, the prescribed dosage of disopyramide in our hospital rarely exceeds 1,200 mg/day, even for patients with refractory ventricular arrhythmias. Whether atypical ventricular tachycardia will be noted in patients taking conventional therapeutic doses of disopyramide remains in question. We have no data on the incidence of atypical ventricular arrhythmias with disopyramide toxicity, but we agree with Parizel and Ranquin that they are not common.

SPONTANEOUS RUPTURE OF ABDOMINAL ANEURYSM

Young et al.[1] point out that the spontaneous rupture of an abdominal aneurysm into the inferior vena cava may be predicted by certain clinical characteristics, but do not mention the electrocardiogram. Pertinent is the report by Dickson et al.,[2] which pointed out that the sudden appearance of electrocardiographic changes consistent with right ventricular overload in patients suffering from an acute abdominal catastrophe should suggest the possibility of an aortocaval fistula, particularly in those with known abdominal aortic aneurysms.

REPLY

New electrocardiographic evidence of right ventricular overload with a rightward shift of axis (usually manifested by the

appearance of an S wave in limb lead I and a small Q wave in lead III) is certainly compatible with the sudden development of a left to right shunt at the systemic level of massive proportion. This finding, additionally, has been noted with compression of the pulmonary artery by a thoracic aortic aneurysm.[1] However, electrocardiographic evidence of right ventricular overload in these clinical settings may indicate other significant pathophysiologic events, such as acute pulmonary emboli. None of the patients reported in our series had this electrocardiographic finding. Because aortic aneurysms will occasionally rupture into vascular capacitance structures, affording time for appropriate diagnosis and therapy, it is important, as we pointed out, that all of the clinical clues leading to this diagnosis be considered.

POSTERIOR AORTIC WALL ECHOGRAM

Tye et al.[1] reported on the usefulness of the aortic root echogram in evaluating the left ventricular compliance. In our study,[2] M mode echocardiography was utilized to investigate the significance of the posterior aortic root movement. Measurement of presystolic posterior motion or *a* wave, total diastolic posterior motion (TDPM) or O to V points and the ratio of presystolic posterior motion to total diastolic posterior motion were measured in 50 normal subjects, 25 patients with mitral stenosis and 35 patients with idiopathic hypertrophic subaortic stenosis. All patients had sinus rhythm. The data are shown in Table I.

In agreement with the results of Tye et al., the ratio of presystolic posterior motion to total diastolic posterior motion of the posterior aortic echogram was found a highly useful index of altered left atrial emptying secondary to decreased compliance of the left ventricle as seen in idiopathic hypertrophic subaortic stenosis. The mean of presystolic posterior motion was somewhat larger in patients with idiopathic hypertrophic subaortic stenosis than in the normal group, but the difference was not statistically significant. However, presystolic posterior motion was significantly smaller among the patients with mitral stenosis whose mitral valve area was less than 1.5 cm^2. This finding is useful in the differentiation of mitral stenosis and other conditions resulting in a decreased E-F slope of the anterior mitral valve particularly when the posterior leaflet is not well recorded. We have also performed similar measurements in patients with hypertension, myocardial infarction and aortic stenosis.

In disagreement with the results of Tye et al., we did not find a uniform correlation between an abnormal ratio of presystolic posterior motion to total diastolic posterior motion and an elevated left ventricular end-diastolic pressure. This was particularly true in the group with coronary artery disease in whom other factors, particularly abnormal early diastolic relaxation of the left ventricle, may alter early diastolic filling without altering left ventricular end-diastolic pressure. That altered left ventricular filling can occur with normal left ventricular end-diastolic pressure was previously shown.[3]

There are also some limitations to these measurements. Presystolic posterior motion is absent in patients with atrial fibrillation. This measurement is also not reliable if the heart rate exceeds 85 beats/min because mid diastolic diastasis is no longer present. Also in the presence of significant atrioventricular block the presystolic posterior motion will overlap with rapid atrial emptying, which would invalidate the measurements. Finally, we have found that dilatation of the left ventricle may also render this measurement less reliable. Despite these limitations, measurements of the presystolic posterior motion and the ratio of the presystolic posterior motion over total diastolic posterior motion is simple and useful clinically.

Yu-Chen Lee, MD, FACC
Frederick J. Sutton, MD
Department of Medicine
University of Maryland
School of Medicine
Baltimore, Maryland

TABLE I

Measurement of Presystolic Posterior Motion (PSPM) and Ratio of Presystolic Posterior Motion to Total Diastolic Posterior Motion (PSPM/TDPM) of the Posterior Aortic Root Movement in Normal Subjects and Patients With Mitral Stenosis or Idiopathic Hypertrophic Subaortic Stenosis

	PSPM (mm)	PSPM/TDPM
Normal subjects	3.4 ± 0.9	0.3 ± 0.07
Mitral stenosis	1.9 ± 0.7 ($p < 0.05$)	0.3 ± 0.06 (NS)
Idiopathic hypertrophic subaortic stenosis	4.8 ± 0.2 (NS)	0.7 ± 0.2 ($p < 0.005$)

NS = not significant; p = probability.

REPLY

We were pleased to learn that Lee and Sutton have confirmed our impression that the echographic aortic root A/OV value is useful for assessing left ventricular function: (1) Since their study group was composed of normal subjects and patients with mitral stenosis or idiopathic hypertrophic subaortic stenosis it is obvious that these cases were preselected and not consecutive. (2) It is not surprising that mitral stenosis or for that matter any disease associated with left atrial dysfunction might not produce a large presystolic *A* wave. (3) We did not claim a "uniform" correlation between the A/OV ratio and elevated left ventricular end-diastolic pressure. The correlation coefficient was 0.75 for these measurements and three subjects with an elevated filling pressure had an A/OV ratio of less than 0.5. (4) It is no revelation to learn that atrial fibrillation is associated with an absent *A* wave. (5) Significant atrioventricular block need not completely nullify the A/OV measurement since random distribution of P-R intervals ranging from 0.12 to 0.20 second may permit hemodynamic evaluation. (6) Our patients represented a study group undergoing elective cardiac catheterization. We will be in-

terested in data provided by Lee and Sutton correlating mean pulmonary wedge pressures and A/OV values in patients with acute myocardial infarction.

VENTRICULAR FIBRILLATION DURING ERGONOVINE MALEATE PROVOCATION OF CORONARY ARTERIAL SPASM

Numerous reports have stressed the safety of administration of ergonovine maleate in the diagnosis of variant angina. However, the recent letter to this Journal by Bauman,[1] which documented a case of recurrent ventricular tachycardia during ergonovine testing, emphasized the possible hazards of this procedure. That Bauman's experience is not unique is evidenced by a similar experience in our laboratory, in which ventricular fibrillation developed in a patient. To our knowledge, this arrhythmia has not been previously reported in the context of provocative testing with ergonovine.

Case report: A 59 year old black woman with an 8 month history of nonexertional chest pain was referred for evaluation. Treadmill stress testing had revealed 3 mm S-T segment depression in a single monitoring lead. Repeat stress testing, with 12 lead monitoring, elicited both S-T depressions and elevations after 6 minutes of exercise; these changes were unaccompanied by angina. After termination of exercise, the patient began to note pain and the electrocardiogram demonstrated S-T elevation in leads V_1, III and aVF. The pain and electrocardiographic changes resolved with administration of sublingual nitroglycerin. Subsequent cardiac catheterization on May 5, 1977 revealed essentially normal coronary arteries and a normally contracting left ventricle.

Provocative testing with ergonovine maleate was then performed, with an initial dose of 0.2 mg administered intravenously over 1 minute. Within 4 minutes the patient noted onset of anginal pain, and the electrocardiographic monitor showed S-T segment elevations. Injections of contrast medium into the left coronary artery were uneventful and revealed complete occlusion of the left anterior descending artery and 80 to 90 percent occlusion of the proximal left circumflex artery. The catheter was rapidly positioned in the ostium of the right coronary artery and injection of approximately 2 to 3 cc of contrast agent showed high grade diffuse spasm of the entire right coronary system. During this injection ventricular tachycardia suddenly developed and rapidly deteriorated to ventricular fibrillation. Electrical cardioversion immediately reestablished sinus rhythm. Intravenous administration of nitroglycerin (8 mg in 250 ml of 5 percent dextrose in distilled water) was begun as soon as the arrhythmia was noted, and lidocaine was administered. The patient had no further rhythm disturbance. Repeat angiography revealed complete relief of coronary spasm and return of the coronary anatomy to the normal appearance seen before administration of ergonovine. The patient's subsequent hospital course was uneventful. Follow-up electrocardiograms and serum isoenzyme determinations confirmed the absence of myocardial infarction, and monitoring revealed no arrhythmia.

Comment: This case and that of Bauman clearly indicate that potentially life-threatening complications can occur with the use of provocative testing with ergonovine maleate. Fortunately, the overall frequency of these complications is apparently low, in light of the paucity of published reports. However, it is important to recognize the risks involved and to take steps to minimize them. Our patient was given 0.2 mg of ergonovine intravenously, a dose that conformed to published recommendations[2–4] found at that time. Other investigators[5,6] utilized smaller doses, and more recent reports[7,8] have suggested that the safety of the test is enhanced with the use of a very small initial dose (0.05 mg), progressing in graduated sequence to a larger dose if no response is elicited in 3 to 5 minutes. This is now standard protocol in our laboratory.

Additionally, our experience illustrates the need to have a parenteral vasodilator immediately available: The patient may lose consciousness as a result of arrhythmia and may be unable to take sublingual nitroglycerin, or the urgency of the situation may demand more rapid reversal of spasm than is afforded by the sublingual route. The case reported by Bauman may be an illustration of this point: the persistence of arrhythmias, pain and S-T elevation, and the occurrence of a response only after administration of three sublingual nitroglycerin tablets, suggests that a more rapid mode of administration would have been desirable. Intravenous nitroglycerin or sodium nitroprusside would be equally satisfactory for this purpose. We used direct intracoronary injection of nitroglycerin in one patient (because of severe pain and electrocardiographic changes persisting more than 2 minutes despite intravenous administration of nitroglycerin) and observed rapid resolution of spasm thereafter. This route might be considered in any patient having serious arrhythmias continuing even after intravenous administration of a vasodilator. We hope that the precautions and suggestions offered here may help avoid the "rare instances of irreversible complications" with ergonovine provocation of which Bauman forewarns.

MOBITZ TYPE II HIS-PURKINJE BLOCK DURING HIS BUNDLE PACING

Castellanos and co-workers[1] recently reported second degree block in the His-Purkinje system demonstrated by His bundle pacing. In their case the block was of the Wenckebach type with a 2:1 ratio. In this letter we present tracings obtained from a patient in whom Mobitz type II His-Purkinje block was seen during His bundle pacing.

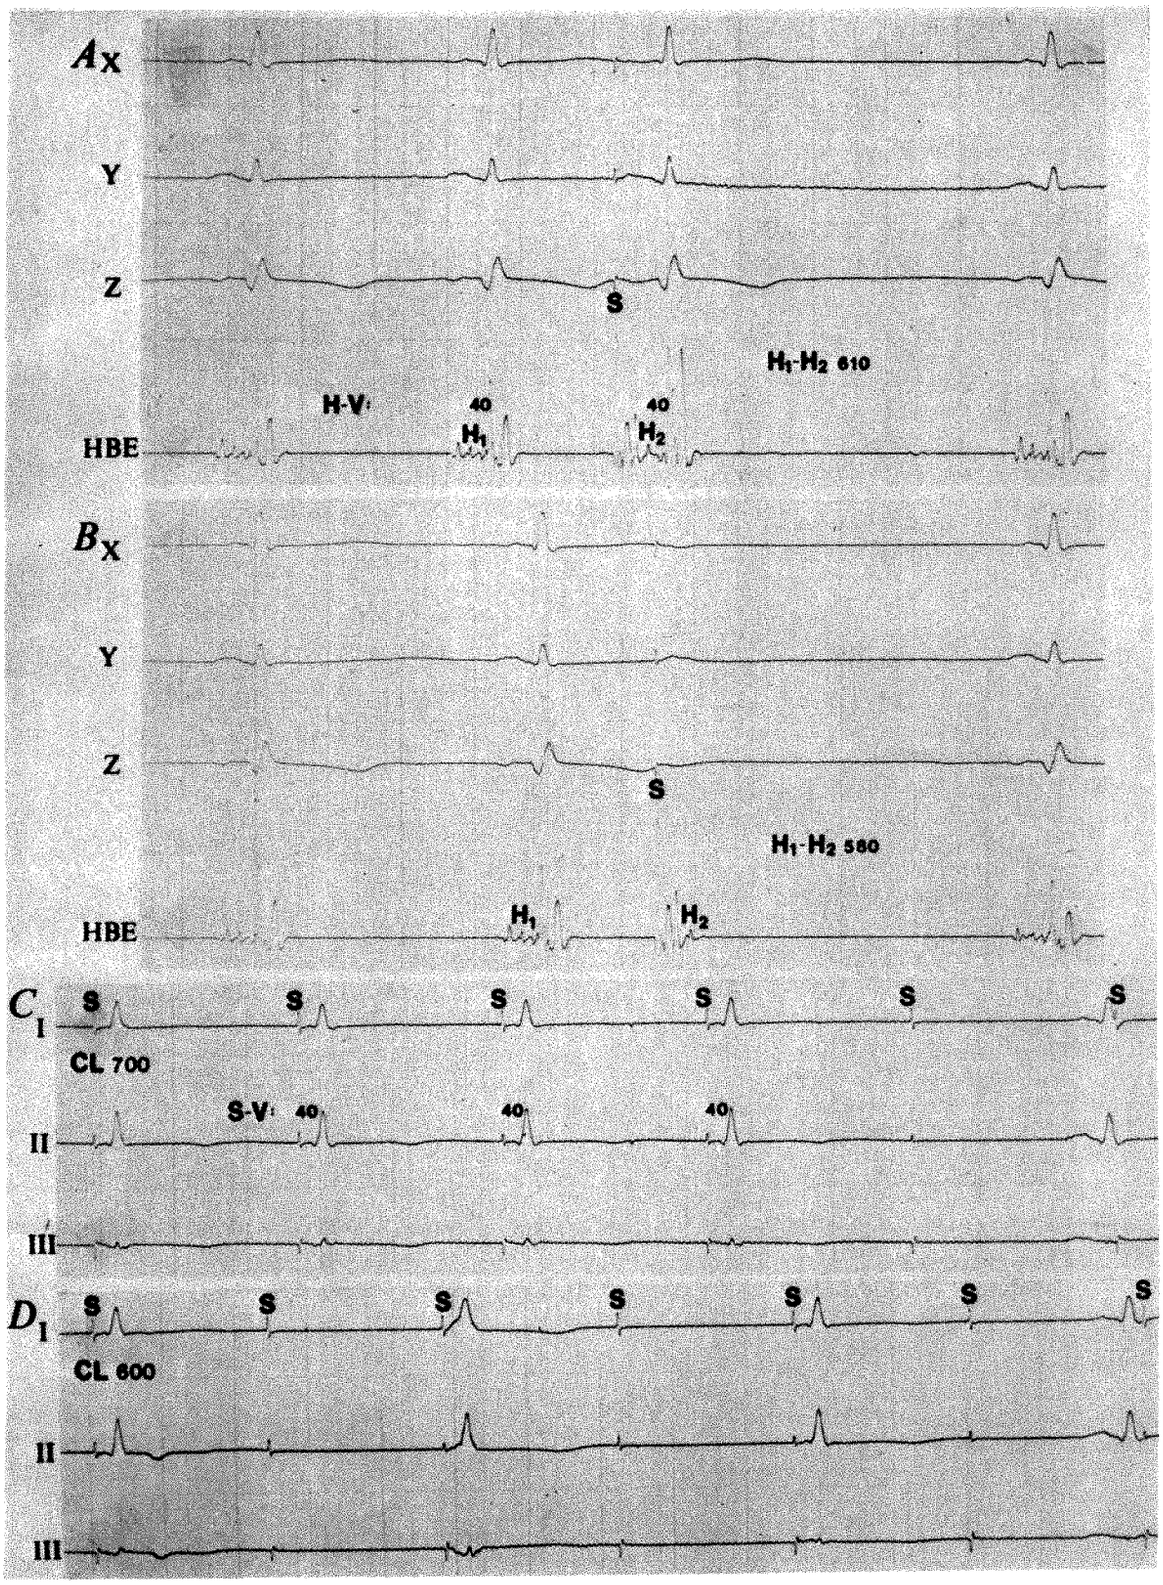

FIGURE 1. Prolonged effective refractory period and Mobitz II block of the His-Purkinje system in a patient with normal H-V time and narrow QRS complexes. **A** and **B**, programmed atrial stimulation. **C** and **D**, His bundle pacing. CL = cycle length; HBE = His bundle electrocardiogram; I, II, and III = standard electrocardiographic leads; S = stimulus artifact; X, Y and Z = Frank orthogonal leads. The intervals are expressed in ms-s. Paper speed 100 mm/s.

Case report: Electrophysiologic evaluation of a 61 year old man was performed because of dizzy spells. The electrocardiogram on admission disclosed sinus arrhythmia with a P-R interval of 0.12 second and narrow QRS complexes. The effective refractory period of the His-Purkinje system, as delineated by programmed atrial stimulation, was 610 ms (panels A and B, Fig. 1). During early atrial extrastimulation no H-V prolongation was seen (panel A). His bundle pacing with a cycle length of 700 ms produced type II His-Purkinje block (panel C), whereas with a cycle length of 600 ms regular 2:1 His-Purkinje block occurred (panel D).

In summary, the following two characteristics of this case are noteworthy: (1) His bundle pacing at a given frequency produced type II His-Purkinje block. (2) In spite of the normal H-V interval and narrow QRS complexes, the effective refractory period of the His-Purkinje system was prolonged.

COMMENT

We agree that this illustration may show a Mobitz II type His-Purkinje block during his bundle pacing. In addition, it also demonstrates some of the difficulties (discussed in our article) encountered when stimulation of the bundle of His is attempted without the simultaneous recording of atrial and ventricular electrograms.

For example, in panel D the third stimulus paced the His bundel as well as the atria, as determined by the distortion of the baseline that occurred before the inscription of the corresponding ventricular complex. On the other hand, in panel C the first four stimuli paced the His bundle, but were not followed by a distorted baseline. This suggests, but does not prove, that the atria were activated by the impulse emerging from the atrioventricular (A-V) node in a retrograde direction. The latter assumption is reinforced by the appearance of the slower sinus P waves only after pacing was stopped. The fact that the fifth stimulus was not followed by a P wave or QRS complex can be explained by selective stimulation of the proximal His bundle with anterograde His-Purkinje block and retrograde A-V nodal block, or by the inability to pace the His bundle because of a sudden increase in its effective refractory period.

A more likely explanation is that the electrodes were displaced "downward" into the right ventricular cavity, as indicated by the slight shift of the axis of the stimulus to the left, determined by the decrease in size of the stimulus in lead II. However, the latter may also reflect a movement of the electrodes away from the right septal surface. Therefore absence of the QRS complex after this stimulus could have been an "artifactual" (pseudo) type II Mobitz block.

MITRAL REGURGITATION

Yoran et al.[1] recently presented data from an experimental model of mitral regurgitation that emphasized the dynamic quality of the regurgitant orifice and subsequent variation of the regurgitant volume. A decrease in the regurgitant orifice and regurgitant volume was reasoned to be due to a reduction in ventricular volume from venodilation produced with nitroprusside or from augmented myocardial contractility.[2]

For a historical perspective, I call attention to an earlier work by Jose et al.[3] Using the double dye-dilution technique, they measured regurgitant flow and forward flow in patients with mitral regurgitation before and after raising or lowering arterial pressure with vasoactive drugs. In subjects with mitral anular dilatation and nonstenotic valves, a positive inotropic stimulus reduced both regurgitant flow and calculated regurgitant orifice.

REPLY

The comment is well taken. In our recent work (Ref 2 of Wong) dealing with the effects of increased myocardial contractility on acute experimental mitral regurgitation, we cited the pioneering work of Jose et al. (Ref 3 of Wong). It is worth noting that our conclusions, which are based on direct measurement of transmitral flow, are in agreement with those of Jose et al., who used the double dye-dilution technique.

CALENDAR OF EXTRAMURAL PROGRAMS

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the National Committee of Continuing Education assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The National Program Committee for Continuing Medical Education of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

Leonard S. Dreifus, MD, FACC
Chairman, Continuing Education Committee
for Extramural Programs

Programs and faculty are subject to change. For further information write Registration Secretary, Extramural Programs Department, American College of Cardiology, Heart House, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

MARCH THROUGH MAY 1980

To be arranged individually — **Preceptorships in Cardiology.** Arthur Seizer, FACC, director, Pacific Medical Center, San Francisco, CA

To be arranged individually — **Preceptorships in Cardiology.** Jules Constant, FACC, director. Buffalo General Hospital, Buffalo, NY

MAR. 24–28 — **Thirteenth Annual Seminar. Electrocardiographic Interpretation of Complex Arrhythmias: A Physiological Approach.** Charles Fisch, FACC and Douglas P. Zipes, FACC, directors. Indiana University Medical Center, Indianapolis, IN

APR. 7–16 — **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC and James E. Crockett, FACC, directors. Rancho Santa Fe Inn, Rancho Santa Fe, CA

APR. 9–12 — **Coronary Artery Disease: A Comprehensive Review.** James S. Forrester, FACC, director. Century Plaza Hotel, Los Angeles, CA

APR. 14–18 — **Consultant's Course in Cardiology.** Louis E. Teichholz, FACC, Richard Gorlin, FACC, Simon Dack, FACC and Ephraim Donoso, FACC, directors. Mt. Sinai Medical Center, New York, NY

APR. 16–18 — **Vectorcardiography—Basic Workshop.** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, AZ

APR. 21–23 — **Practical Cardiology for the Family Physician.** Robert S. Eliot, FACC, director. Marriott Hotel, San Antonio, TX

APR. 24–26 — **The Pathology of Congenital Heart Disease.** Maurice Lev, FACC, Jesse E. Edwards, FACC and Saroja Bharati, FACC, directors. Palmer House, Chicago, IL

APR. 25–27 — **New Concepts in Clinical Electrocardiography.** William J. Mandel, FACC and Irwin Hoffman, FACC, directors. Beverly Hilton Hotel, Beverly Hills, CA

May 1–3 — **Problems in Management of Valvular and Ischemic Heart Disease.** Leonard G. Christie, Jr., FACC, Carl J. Pepine, FACC and C. Richard Conti, FACC, directors. Harstan Convention Center, Innisbrook Resort and Golf Club, Tarpon Springs, FL

MAY 3–6 — **Fifth Annual Symposium on Cardiovascular Nursing.** Henry J. L. Marriott, FACC and Leo Schamroth, FACC, directors. Carillon Hotel, Miami Beach, FL

MAY 7–9 — **Clinical Auscultation of the Heart.** W. Proctor Harvey, FACC, director and Antonio C. deLeon, Jr., FACC and John F. Stapleton, co-directors. Georgetown University Medical Center, Washington, DC

MAY 12–14 — **Trends in Cardiology (With Emphasis on Coronary Atherosclerotic Heart Disease).** J. Willis Hurst, FACC, director and Robert C. Schlant, FACC, co-director. Sheraton Atlanta Hotel, Atlanta, GA

MAY 15–17 — **Acute Myocardial Infarction: Recognition—Management—Rehabilitation.** Arthur Selzer, FACC and Keith E. Cohn, FACC, directors. The St. Francis Hotel, San Francisco, CA

MAY 21–23 — **Diagnosis and Treatment of Dysrhythmias in Children.** Paul C. Gillette, FACC, Arthur Garson, Jr. and Dan G. McNamara, FACC, directors. Texas Children's Hospital, Houston, TX

LEARNING CENTER: PROGRAM CALENDAR

The American College of Cardiology's newest department, the Learning Center, located at the College's Bethesda Maryland headquarters, began operations in October 1977 with the offering of its first continuing medical education program for physicians with a specialty or an interest in cardiovascular medicine. The purpose of the Learning Center is to support the professional commitment to quality patient care by providing a new standard of excellence in cardiovascular continuing education. For additional information concerning the programs listed below or for a complete schedule of programs through July 1980, contact Program Coordinator, Learning Center, American College of Cardiology, 9111 Old Georgetown Road, Bethesda, Maryland 20014. Telephone (301) 897-5400.

MARCH THROUGH JULY 1980

Month/Dates	Program Director	Title of Program
March 24–26	John A. Mantle, MD	**Quality Assurance and Management for Cardiovascular Nurses**
March 27–29	John A. Spittell, Jr., MD	**Peripheral Vascular Disease**
April 9–11	Victor Parsonnet, MD	**Current Concepts in Pacing**
April 14–16	Keith Cohn, MD	**Exercise Testing**
April 21–23	Nanette K. Wenger, MD	**Rehabilitation of the Coronary Patient**
April 28–30	Pravin M. Shah, MD	**M-Mode and 2-Dimensional Echocardiography: Current Status and Future Promise**
May 1–3	Daniel S. Berman, MD	**Nuclear Cardiology**
May 5–7	Robert G. Tancredi, MD	**Management of Pulmonary, Renal and Electrolyte Disorders in Cardiac Patients**
May 12–14	Louis Lemberg, MD	**Cardiology Update for Intensive Care Unit Nurses**
May 19–21	Arthur E. Weyman, MD	**Cross-Sectional Echocardiography**
May 28–30	Elliot Rapaport, MD	**Cardiology for the Consultant**
June 2–4	Borys Surawicz, MD	**Advanced Cardiac Electrophysiology for Cardiologists**
July 14–16	Arthur D. Hagan, MD	**Fundamentals of Clinical Echocardiography for the Non-Echocardiographer**
July 24–26	Victor F. Froelicher, Jr., MD and Paul L. Henry, MD	**Exercise Testing**

30TH ANNUAL SCIENTIFIC SESSION
AMERICAN COLLEGE OF CARDIOLOGY

MARCH 15–19, 1981 SAN FRANCISCO, CALIFORNIA

INSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDI articles devoted to cardiovascular disease. Articles r to THE AMERICAN JOURNAL OF CARDIOLOGY and b Publisher. The Publisher reserves copyright and renew and such material may not be reproduced in any form wi of the Publisher. Statements in articles are the responsil will assist the editors in the prompt processing of manu are followed:

THE WHOLE PAPER

- Address manuscript to Managing Editor, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- Submit two copies of all elements of the article: text, references, legends, tables and figures.
- Arrange the paper in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- Number all pages in above sequence, beginning with title page as 1, abstract as 2, etc.
- Type all matter: (1) on $8\frac{1}{2} \times 11$ opaque white bond paper; (2) in duplicate; (3) on one side of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- Include first names, degrees and, where applicable, FACC for all authors.
- Provide a short running title of 3 to 6 words.
- Insert at bottom: name and address of institution from which work originated plus information about grants.
- Add at bottom the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- Limit words as follows: 100 to 250 words for major articles; 50 to 100 words for case reports.
- Add at end of abstract: list of 2 to 6 key words and subjects for indexing.

THE TEXT

- Type in duplicate; double-space.
- Do not use abbreviations such as SVC, WPW: write out superior vena cava, Wolff-Parkinson-White.
- Abbreviate measurements (mm, kcal and the like) as recommended in *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, published in *Am Rev Respir Dis* 1979; 119:3–10; *Ann Intern Med* 1979; 90:95–9; *Br Med J* 1979; 1:532–5; and *Lancet* 1979:1:428–30.
- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each merals: Table tables in order the text.
- Provide a fe fying in alphal used.

THE FIGUF

- Submit 2 glo photo and dra
- Please note cles will not be
- Use black ir Make decima enough for rep
- Use arrows
- Crop photo sential field.
- Identify figu thor's name.
- Number figu mentioned in t
- Indicate top
- Submit writt and author to r lished figures.
- Limit figures ity. The publish reproduction.

butrex®
utamine HCl
For Short-Term
Support in Patients with
utput Cardiac Failure

Selectively Increases
Myocardial Contractility
with Consistent
Hemodynamic Improvements

Dobutrex®
Dobutamine HCl

For I.V. Injection
250 mg* in 20-ml-size vials
* Equivalent to dobutamine

Brief Summary
Consult the package literature for prescribing information.

Indications and Usage: Dobutrex® (dobutamine hydrochloride, Lilly) is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to instituting therapy with Dobutrex.

Contraindication: Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

Precautions: 1. **During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.**

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

Usage Following Acute Myocardial Infarction—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex® (dobutamine hydrochloride, Lilly) for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

Administration and Dosage: *Reconstitution and Stability*—Dobutrex® (dobutamine hydrochloride, Lilly) is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add an additional 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstituted time periods stated above.

Recommended Dosage—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250,500, and 1000 mcg/ml

Drug Delivery Rate (mcg/kg/min)	Infusion Delivery Rate 250 mcg/ml* (ml/kg/min)	500 mcg/ml† (ml/kg/min)	1000 mcg/ml‡ (ml/kg/min)
2.5	0.01	0.005	0.0025
5	0.02	0.01	0.005
7.5	0.03	0.015	0.0075
10	0.04	0.02	0.01
12.5	0.05	0.025	0.0125
15	0.06	0.03	0.015

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

Thanks to a CyberLith™ pacemaker Connie's life is back on track.

FOR PATIENTS, LIKE CONNIE, WHO DON'T RESPOND TO DRUG THERAPY, A CYBERLITH CAN PROVIDE A NORMAL, ACTIVE LIFE.

Less than four months after her pacemaker implant Connie Yanosick finished 98th out of 409 participants in an annual nationally sponsored 6.2 mile race. Connie is an active young woman. She is assistant coach of the women's basketball team at Mount Aloysius College in Cresson, Pennsylvania, where she is studying to be an occupational therapist assistant. She is also a resident advisor in her dormitory and treasurer of the school's Occupational Therapy Club.

Like any college student, Connie enjoys visiting with her friends for late-night talk sessions. Classmates majoring in nursing frequently check Connie's pulse just to experience what they term the pacemaker "click-in." A member of an athletic family, twenty-year-old Connie still rough-houses with her siblings who don't consider her to be "fragile or different."

Obviously, Connie is a happy, healthy young woman. Her bradycardia is controlled by a CyberLith. Of course her personal lifestyle will change over the coming years. But the multi-programmable CyberLith will permit her physician to accommodate her changing physical requirements. We feel very certain that Connie will experience a lot of living in the future.

Connie's CyberLith is just one model in the growing family of specialized CyberLith pacemakers. Thin and lightweight, CyberLith pacemakers permit noninvasive adjustment of stimulation rate, pulse width, sensitivity level and pacing mode. And, the CyberLith has a longer history of reliability than any other programmable multi-parameter pacemaker line. CyberLith put Connie back on track. It could be the pacemaker of choice for your patients.

INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacemaking are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting with intractable, recurrent, congestive heart failure, cerebral or renal insufficiency; or recurrent, drug-resistant tachyarrhythmias who have been shown to benefit from temporary cardiac pacing are considered candidates for permanent cardiac pacemaking.

The indications for permanent pacing in the presence of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, mechanism of the arrhythmias, and response to therapy. In general, symptomatic drug-resistant bradyarrhythmias which impair cardiac output are considered indications for pacing in patients with acute myocardial infarction, regardless of infarct location.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. However, body rejection phenomena such as local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

CAUTION: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

NOTE: The CyberLith and the CyberLith Programmer are currently undergoing clinical evaluation.

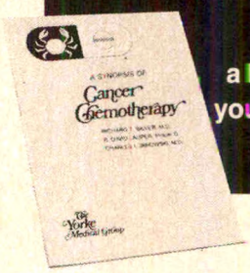
How to Keep Up with Drug Interaction in Cancer Chemotherapy



Three authorities from a leading medical center show you how to use the most current chemotherapeutic agents

A SYNOPSIS OF
Cancer Chemotherapy

At last a way to keep up with the bewildering proliferation of new chemotherapeutic drugs which have come into use relatively recently. This just published guide will be valuable to every hospital, and every oncology specialist, general internist, clinical pharmacist, and nurse oncologist.

A SYNOPSIS OF CANCER CHEMOTHERAPY is a concise, readily understandable "how to" manual. Developed originally for staff use at The New York Hospital-Cornell Medical Center, the concept proved so successful it was decided to make it available to other professionals. The new users of the SYNOPSIS have the advantage of a proven, time-tested learning system. It is written in a unique, compact work-book style to keep reading time to a minimum.

The reader can quickly find the following for both commercially available and investigational drugs:

- Structure
- Mechanism of Action
- Pharmacokinetics
- Toxicity
- Therapy
- Availability

The chemotherapeutic agents in the main listing section cover these categories:

- Alkylating Agents
- Antimetabolites
- Mitotic Inhibitors
- Antibiotics
- Miscellaneous (includes such drugs as Mithramycin, Mitotane, etc.)

RICHARD T. SILVER, MD, F.A.C.P., F.A.B.C.O.
Chief, Oncology Service, Div. Hematology-Oncology, Clinical Professor of Medicine, Cornell University Medical College, Attending Physician, New York Hospital, Exec. Officer, Cancer & Leukemia Group B.

R. DAVID LAUPER, Pharm. D.
Asst. Director for Education and Information, Pharmacy Dept., New York Hospital-Cornell Medical Center.

CHARLES I. JAROWSKI, MD
Instructor in Medicine, Cornell University Medical College, Senior Chemotherapy Fellow, Div. of Hematology-Oncology, The New York Hospital.

Use it for 30 days—FREE

Refer to it for chemotherapeutic drug information for a full month. Then keep the book only if you want it for permanent reference. Otherwise simply return it and owe nothing. You have nothing to lose and a whole world of valuable life-saving knowledge to gain. Order right now!

1980. A NEW ERA OPENS IN CRITICAL CARE.

The new CRITIKON

The company totally committed to critical care.

To create the new Critikon, Johnson & Johnson consolidated these established critical care names and product lines into one company:

- **The complete product lines of Jelco Laboratories and Applied Medical Research.**
- **Blood/gas monitors from Critikon Division, McNeil Laboratories.**
- **I.V. infusion pumps and Lanz™ tracheal tubes from Extracorporeal Medical Specialties.**

This concentration on critical care medicine has some special benefits for you and your patients.

For instance, our sales force is now unified and expanded. Each representative now covers a smaller area, has more time to devote to your critical care needs, and is closer than before when you need quick service.

By combining our research teams, we can expand our R & D programs, develop new and better products, and improve cost effectiveness.

And we promise you this—we will service what we sell. If Critikon medical electronic equipment should need servicing, we will handle it on the spot or at one of our new regional service centers.

Bigger can mean better. And stronger. Better products and a stronger service capability for all of your needs. Critikon—our commitment is to critical care.

Write or call for more information: Critikon, Inc., P.O. Box 22800, Tampa, FL 33622. 800-526-3928 (In New Jersey: 201-524-2555.)

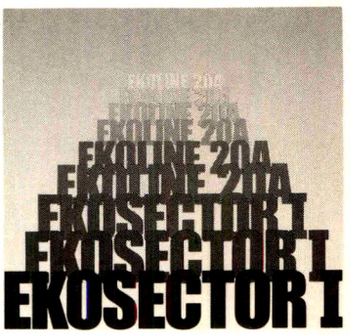
Announcing the SKI M-mode to Real-time Conversion Program.

A unique opportunity for owners of the Ekoline 20A®.



There'll never be a better time to expand your M-mode system to scanning.

Here's what we'll do to help.

We will exchange your Ekoline 20A M-mode system for a new factory assembled and calibrated EkoSector I® two-dimensional scanning system with a full one-year warranty at a price which is bound to match your needs and budget. And to make your procedures easier and faster, you get at no extra charge our M-mode Transducer Kit and 30° High Resolution Probe Head.

Take advantage of this special offer today.

For more details, call toll-free 800-538-1556. In California, call collect 408-732-6000. Or return this coupon.

For steady maintenance.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

- ☐ Greater GI tolerance than with quinidine sulfate
- ☐ Full quinidine cardiodynamics
- ☐ Convenient b.i.d. or t.i.d. dosage for most patients

CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of a broad range of cardiac arrhythmias (see Brief Summary). After conversion to normal sinus rhythm —whether with CARDIOQUIN Tablets or electroconversion— only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required for maintenance in most cases. The polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*viado, D. M., Krantz and Carr's Pharmacologic Principles of Medical ctice, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heart-block; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 100.
